Abstract

We develop a methodology for writing interactive and object-based programs (in the sense of Wegner) in dependently typed functional programming languages. The methodology is implemented in the ooAgda library. ooAgda provides a syntax similar to the one used in object-oriented programming languages, thanks to Agda's copattern matching facility. The library allows for the development of graphical user interfaces (GUIs), including the use of action listeners.

Our notion of interactive programs is based on the IO monad defined by Hancock and Setzer, which is a coinductive data type. We use a *sized* coinductive type which allows us to write corecursive programs in a modular way. Objects are server-side interactive programs that respond to method calls by giving answers and changing their state. We introduce two kinds of objects: simple objects and IO objects. Methods in simple objects are pure, while method calls in IO objects allow for interactions before returning their result. Our approach also allows us to extend interfaces and objects by additional methods.

We refine our approach to state-dependent interactive programs and objects through which we can avoid exceptions. For example, with a state-dependent stack object, we can statically disable the pop method for empty stacks. As an example, we develop the implementation of recursive functions using a safe stack. Using a coinductive notion of object bisimilarity, we verify basic correctness properties of stack objects and show the equivalence of different stack implementations. Finally, we give a proof of concept that our interaction model allows to write GUI programs in a natural way: we present a simple drawing program, and a program which allows the users to move a small spaceship using a button.

Note: We recommend printing this paper in color.

1 Introduction

Functional programming is based on the idea of reduction of expressions. This is a good notion for writing batch programs which take a fixed number of inputs to compute a fixed number of outputs. Interactive programs, however, do not fit directly into this paradigm since they are programs which over time accept a possibly infinite number of inputs and respond in sequence with a possibly infinite number of outputs. There are several ways to overcome this. In functional programming, the main method currently used is Moggi's IO monad (Moggi, 1991). The IO monad is a type (IO a) of computations depending on a return type a. Its elements are interactive programs which possibly terminate with a result of type a. It is an open-ended type: Programming languages such as Haskell provide various functions constructing atomic elements of (IO a) for various types a, and the bindings >>= :: IO a -> (a -> IO b) -> IO b and return :: a -> IO a are used to construct programs from these atomic operations.

In a series of articles (Hancock & Setzer, 2000a; Hancock & Setzer, 2000b; Setzer & Hancock, 2004; Hancock & Setzer, 2005), Hancock and the third author of this article have developed a representation of interactive programs in dependent type theory. This approach is based on the notion of a coalgebra. The idea is that a (client-side) interactive program is represented by a possibly non-well-founded tree. The nodes are labeled with commands being issued to the real world, and the subtrees of a tree are labeled with responses from the real world to the respective command. For instance, if a node is labeled with the command *input a string*, its subtrees would be indexed over strings the user has entered; if the command is *write a character*, the response would be an element of the singleton type Unit, so there is only one subtree.

Execution of an interactive program thus is no longer the simple reduction of an expression. Instead, it is performed as follows: one computes a label from the root of the tree. A corresponding program is executed in the real world. The real world returns a corresponding response. Then, the subtree labeled with this response is chosen, and one repeats the same procedure for the root of that subtree. Additionally, there are special nodes called leaves, labeled by an element of the result type of the interactive program. If we reach such a leaf, the program terminates returning the label. The monadic operations *bind* and *return* can now be defined in a straightforward way as operations on such trees.

If we define trees by inductive data types (Agda keyword data), we obtain only well-founded trees, which means trees which have no infinitely deep branches. Interactive programs correspond to non-well-founded trees because they may run forever if never terminated. A non-well-founded tree can be represented in Agda by a record which is coinductive.

The programs discussed above were client-side interactive programs: They send a command to the real world and then receive a response and continue. In contrast, graphical user interfaces (GUIs) are server-side programs; they wait for an event—such as a click on a button—which means they wait for a command from the real world, answer with a result and then wait for the next command. Similarly, objects are ready to accept any call of a method. In response, they return a result, and the object changes its state. Based on this idea, the third author has developed (Setzer, 2006) the theory of defining object-based programs (in the sense of Wegner (1987)) in dependent type theory. The interaction trees of server-side programs and objects are functors of the form $\Pi\Sigma$ (meaning for all requests, return some response),

rather than $\Sigma\Pi$ (send some request and react to any response) as for client-side programs.

The goal of this article is to substantially extend this theory and develop a methodology for actually implementing interactive and object-based programs in Agda in a user-friendly way. This will include object-based GUIs. We have developed the library oo Agda (Abel et al., 2016), which allows writing objects and interactive programs in a way that is very close to how it would be done in an object-based programming language. At this stage, inheritance and subtyping are not available in ooAgda, so ooAgda is currently an object-based library. Using illustrative examples, we will show how oo Agda can be used for writing interactive programs which make use of objects. The simplest example will be a program which interacts with a cell containing a string via its methods put and get. Then, we will look at how to extend an object by adding more methods and extending its implementation. Furthermore, we will look at state-dependent interactive programs and objects. This allows us to write a safe stack, where popping is only allowed if the stack is non-empty; by safe we mean we can avoid exceptions. We will introduce bisimulation as equality, and show that the operations of put and get are inverse to each other w.r.t. bisimulation. We also show the equivalence of different stack implementations.

So far, in dependent-type theory, not many interactive programs have been written. We prove that it is possible to write graphical interfaces by presenting two examples. The first one is a simple drawing program. The second example will be a GUI having one button. In this example, we will make use of an object, which has action listeners as methods, which in turn will be added to a button event and a repaint event. Note that the focus here is not on developing advanced user interfaces, but to demonstrate that one can use objects and action listeners to develop GUIs in dependently typed programming.

The content of this article is as follows: In Section 2, we give a brief introduction into Agda. In Section 3, we recapitulate the theory of coalgebras and their representation in Agda. Then, we review (Section 4) the theory of interactive programs in Agda. In Section 5, we introduce objects in Agda and write a small interactive program which makes use of an object representing a cell.

Guarded recursion (Coquand, 1994) allows only recursive calls of the following three forms: direct recursive calls to the function being defined, an expression which was defined before the function was defined, or constructors applied to the previous two possibilities. In particular, we cannot use functions to combine elements of the coalgebra to form new elements of it. This restricts modularity of programs since one cannot use an auxiliary function in a corecursive call. Instead, one needs to define a new function simultaneously with the function to be defined which computes the result of applying the auxiliary function to its arguments. The function

In their simplest form, exceptions can be represented by using the Maybe type. This corresponds to its standard use: If we have an unsafe stack, we would need to, in case we pop from an empty stack, return a result, although we do not have an element of the type of stack elements given. One can solve this by using as result type for pop the Maybe type, and returning in case one pops from the empty stack the element nothing, which represents an exception. When using the result of the pop operation, one needs to deal with the case that the result could be such an exception, i.e., nothing, which amounts to a form of exception handling.

is defined exactly like the auxiliary function, repeating essentially its definition. This makes programming tedious. In Section 6, we discuss how sized types allow for corecursive programs to be written more naturally. With sized types, such auxiliary functions are allowed in corecursive definitions provided they are size-preserving.

In Section 7, we give an example of how to extend an object by adding a new method. In Sections 8.1 and 8.2, we introduce state-dependent objects and show how a stack can be implemented which statically prevents pop-operations when empty. In 8.2.1, we develop a small example of how to implement recursive functions using a safe stack. In Section 8.3, we demonstrate how to define bisimilarity as equality on objects. This equality is used to prove that the push and pop operations are inverse of each other. In Section 8.4, we look at how to define state-dependent interactive programs which will be used later to define a more complex GUI. In the last two sections, we will give examples of how to define GUIs in Agda; in Section 9, we introduce a simple drawing program; in Section 10, we introduce a GUI in which we assign an action listener to a button. There are three versions of this interface. In the most complex one, action listeners are defined as in ordinary object-oriented programming: by creating an object which contains all the required action listeners as methods and associating them with the button and the repaint event.

We finish with a review of related work (Section 11), which includes a comparison of our approach with Brady's work in Idris, and a conclusion with an outlook on future steps (Section 12).

Every line of Agda code provided in this paper has been type-checked by Agda and rendered by the Agda IATEX-backend. However, we mostly omit administrative parts of the code such as modules and namespace handling; thus, the code as printed in this article will not be accepted by Agda as is. Relative to the correctness of Agda itself, our code is type-safe. However, we see the need for a more solid theoretical foundation for Agda's sized types (Section 6). The complete code, including advanced examples, can be found in Abel *et al.* (2016). These examples compile to executable binaries using Agda 2.5 and GHC 7.8.

2 Introduction to Agda

Agda (Agda Wiki, 2016; Stump, 2016) is a theorem prover based on intensional Martin-Löf type theory (Martin-Löf, 1984). Code can be compiled using the MAlonzo compiler (Agda Wiki, 2011), which is a *Monadic* form of the Alonzo compiler (Benke, 2007); therefore, Agda can also be seen as a dependently typed programming language. It is closely related to the theorem prover Coq (2015). Furthermore, Agda is a total language, which is guaranteed by its termination and coverage checker without which Agda would be inconsistent. The current version of Agda is Agda 2, which was originally designed and implemented by Ulf Norell in his PhD thesis (2007).

In Agda, there are infinitely many levels of types: The lowest one is called Set. The next type level is called Set₁, which has the same closure properties as Set but also contains Set as an element. The next type level is called Set₂, etc. Furthermore, we can quantify over type levels, and obtain types (Set σ) depending on levels σ .

The main type constructors in Agda are dependent function types, inductive types, and coinductive types. In addition, there exist record types, which are used for defining coinductive types by their observations or elimination rules. Furthermore, there exists a highly generalised version of inductive–recursive and inductive–inductive definitions.

Inductive data types are dependent versions of algebraic data types as they occur in functional programming. They are given as sets A together with constructors which are strictly positive in A. For instance, the even and odd numbers are given by the simultaneous — as denoted by the keyword mutual — indexed inductive data types:

mutual

```
data Even: \mathbb{N} \to \operatorname{Set} where 0p: Even 0 sucp: \{n : \mathbb{N}\} \to \operatorname{Odd} n \to \operatorname{Even} (suc n) data \operatorname{Odd}: \mathbb{N} \to \operatorname{Set} where sucp: \{n : \mathbb{N}\} \to \operatorname{Even} n \to \operatorname{Odd} (suc n)
```

The expression $(n:\mathbb{N}) \to A$ denotes a dependent function type, which is similar to a function type, but A can depend on n. The expression $\{n:\mathbb{N}\} \to A$ is an implicit version of the previous construct. Implicit arguments can be omitted, provided they can be inferred by the type checker. We can make an implicit argument explicit by writing, e.g., (sucp $\{n\}$ p). If there are several explicit or implicit dependent arguments in a type, one can omit " \to ", as illustrated in the following example: $(a:A)(b:B) \to C$ instead of $(a:A) \to (b:B) \to C$. The elements of (Even n) and (Odd n) are those that result from applying the respective constructors. Therefore, we can define functions by case distinction on these constructors using pattern matching, e.g.,

mutual

```
_+e__: \forall \{n \ m\} \rightarrow Even n \rightarrow Even m \rightarrow Even (n + m) Op __ +e__ p = p sucp p_ +e__ q = sucp (p + o \ q)
__+o__: \forall \{n \ m\} \rightarrow Odd n \rightarrow Even m \rightarrow Odd (n + m) sucp p_ +o__ q = sucp (p + e \ q)
```

Here, $\forall a \to B$ is an abbreviation for $(a:A) \to B$, where A can be inferred by Agda. $\forall \{a\} \to B$ is the same but for an implicit argument, while $\forall \{n \ m\} \to B$ abbreviates $\forall \{n\} \to \forall \{m\} \to B$. Agda supports mixfix operators, where "_" denotes the position of the arguments. For instance, $(0p + e \ p)$ stands for $(_+e_0p \ p)$. The combination of mixfix symbols together with the availability of Unicode symbols makes it possible to define Agda code which is very close to standard mathematical notation.

Nested patterns are allowed in pattern matching. The coverage checker verifies completeness and the termination checker ensures that the recursive calls follow a schema of extended primitive recursion.

An important indexed data type is propositional equality $x \equiv y$ (for x, y : A) which has as constructor a proof of reflexivity:²

```
data _{=} _{=} \{a\} \{A: Set a\} (x:A): A \rightarrow Set a where refl: x \equiv x
```

This definition says that propositional equality is the least reflexive relation (modulo the built-in definitional equality of Agda).

3 Coalgebras in Agda

The approach to interactive programs that we employ in this article is based on (weakly) terminal coalgebras. In this section, we recapitulate coalgebras and their definition in Agda, first by example, then in the general case.

3.1 Coalgebra by example: Colists

Coalgebras are a versatile mathematical tool; for instance, they can model various classes of transition systems. Here, we consider *output automatons*, which consist of a (not necessarily) finite state set S and a transition function $t:S \to (1+A\times S)$. Given a state s:S, the transition ts can either lead us to termination (type alternative 1) or emit some output a:A and lead us into a successor state s':S (type alternative $A\times S$). Defining the functor $FS=1+A\times S$, we say the pair (S,t) is an F-coalgebra. We may sometimes refer to this coalgebra by simply S or t, when the other component is clear from the context of discourse.

Let us call this functor ListF, for reasons that are apparent to the reader or will become so in a short while, and define it in Agda as a disjoint sum type ListF with two constructors nil and cons:

```
data ListF A S: Set where

nil : ListF A S

cons : (a:A) (s:S) \rightarrow ListF A S
```

It should be clear that (ListF AS) is a faithful implementation of $1 + A \times S$, with nil corresponding to the left injection of the empty tuple, and (cons a s) to the right injection of the pair (a, s).

² By propositional equality we mean the standard equality type as introduced by Martin-Löf. Definitional equality is—as in Martin-Löf's original definition—based on definiens equals definiendum (see, e.g., Nordström et al. (2001, Section 3.5). Due to nested pattern matching, we allow definitions that give more definitional equalities than one would have when reducing the terms to the corresponding recursion combinators. But these definitions are covered by the meaning explanations; therefore, our notion of definitional equality is still in the spirit of Martin-Löf. See for instance the discussion of Martin-Löf (1984, p. 31).

A ListF-coalgebra is now a pair (S,t) of a type S and a function $t:S \to \mathsf{ListF}\ A\ S$ for a fixed type A, and a transition will take us either to nil, meaning the automaton terminates, or cons $a\ s'$, meaning the automaton outputs a and enters the new state s'.

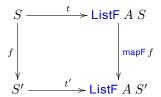

A ListF-coalgebra morphism from automaton $t: S \to \mathsf{ListF}\ A\ S$ to automaton $t': S' \to \mathsf{ListF}\ A\ S'$ is a state map $f: S \to S'$ with two conditions:

- 1. Terminal states of t are mapped to terminal states of t', meaning that t'(f s) = nil whenever t s = nil.
- 2. Non-terminal states of t are mapped to corresponding non-terminal states of t' with the same output, meaning that $t'(f s_1) = \cos a (f s_2)$ whenever $t s_1 = \cos a s_2$.

These two conditions can be summarized as $t'(f s) = \mathsf{mapF} f(t s)$ for all s : S, using the functoriality witness mapF of ListF A:

```
\begin{array}{ll} \mathsf{mapF}: \forall \{A \ S \ S'\} \ (f:S \to S') \to (\mathsf{ListF} \ A \ S \to \mathsf{ListF} \ A \ S') \\ \mathsf{mapF} \ f \ \mathsf{nil} &= \ \mathsf{nil} \\ \mathsf{mapF} \ f \ (\mathsf{cons} \ a \ s) &= \ \mathsf{cons} \ a \ (f \ s) \end{array}
```

Or, for the category-theory enthusiast, we can display this condition in the form of a commutative diagram:

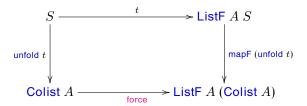

If we run an output automaton t, starting in state s, to completion, we obtain a possibly terminating sequence, aka colist, of outputs a_0, a_1, \ldots . We call this colist unfold t s: Colist A. In Agda, the type of colists over A is defined as a recursive record type:

```
record Colist A: Set where force: ListF A (Colist A)
```

An element l: Colist A is a lazily computed record with a single field force l: ListF A (Colist A); one could also view it as an object with a single method force. Invocation of this method via (force l) will yield either nil or (cons a l') for an output a: A and a new colist l'.

In this sense, the pair (Colist A, force) can be seen as a ListF-coalgebra; any colist l is the state of an output automaton with force as the transition function. Colist A is even the weakly terminal or weakly final coalgebra, as every coalgebra (S,t) can be mapped into it via morphism (unfold t), so there exists a function, unfold $t: S \to \text{Colist } A$, which makes the diagram commute. If we take bisimulation

on Colist as equality, then Colist is actually *terminal* or *final*. This means that (unfold t) is the only function which makes this diagram commute:

The (weak) finality witness unfold can be implemented in Agda as follows. Herein, read the "with ts..." followed by pattern matching as an additional case distinction over (ts): ListF A S. The three dots "..." indicate that the pattern from the previous line is repeated, and "|" starts a pattern related to the term of the with construct:

```
\begin{array}{lll} \text{unfold} & : & \forall \{A \ S\} \ (t : S \rightarrow \mathsf{ListF} \ A \ S) \rightarrow (S \rightarrow \mathsf{Colist} \ A) \\ \text{force (unfold } t \ s) & \text{with } t \ s \\ \dots \mid \mathsf{nil} & = \ \mathsf{nil} \\ \dots \mid \mathsf{cons} \ a \ s' & = \ \mathsf{cons} \ a \ (\mathsf{unfold} \ t \ s') \end{array}
```

This definition is an instance of a function defined by *copattern matching* (Abel *et al.*, 2013). By itself, (unfold t s) does not reduce. Only when we subject it to projection force, it reduces as given by the right hand side of the definition; in this case, to a case distinction over (t s).

Agda's termination checker accepts the recursively defined unfold: Since each recursive call removes one use of force, the reduction cannot continue forever. In fact, this definition follows the rules of guarded recursion (Coquand, 1994). Guarded recursion means in this setting that we can define a function recursively as long on the left-hand side we apply at least one observation (here force) to the function applied to its arguments (of course we need to cover all copatterns). On the right-hand side of the recursive definition, one can have either an element of the coalgebra defined before, a recursive call of the function to be defined, or constructors applied to such a recursive call. An example, which demonstrates that we cannot allow arbitrary functions to be applied to the recursive call, would be the black hole recursive definition $f: A \to \text{Colist } A$, force $(f \ a) = \text{force } (f \ a)$.

The above definition of unfold is equivalent to the generic force (unfold t s) = mapF (unfold t) (t s) obtained from the commutative diagram. However, the latter falls out of the scheme of guarded recursion and termination is less obvious. We will further discuss this issue in Section 3.2.

As an application of unfold, we generate the Collatz sequence. It starts with some number n. If n = 1, the sequence terminates. Otherwise, if n is even, it continues with n/2, and if n is odd, then it continues with 3n + 1. In the following code, "_"

³ It is conjectured that (except for n = 0, which creates an infinite sequence of 0's), the resulting sequence is always finite. But as of today, this conjecture has resisted all proof attempts.

is the Agda notation for an unused argument. The application $(n \operatorname{divMod} m)$ returns (result q r s), with quotient $q = n \operatorname{div} m$, remainder $r = n \operatorname{mod} m$, and a proof s of $n \equiv q * m + r$. Note also that pattern matching is executed in sequence: The pattern (collatzStep n) is only reached if $n \neq 1$:

```
\begin{array}{lll} \text{collatzStep} & : & \mathbb{N} \to \text{ListF } \mathbb{N} \ \mathbb{N} \\ \text{collatzStep 1} & = & \text{nil} \\ \text{collatzStep } n & \text{with } n \text{ divMod 2} \\ \dots \mid \text{result } q \text{ zero } = & \text{cons } n \ q \\ \dots \mid - & = & \text{cons } n \ (1 + 3 \ ^* n) \\ \\ \text{collatzSequence} & : & \mathbb{N} \to \text{Colist } \mathbb{N} \\ \text{collatzSequence} & = & \text{unfold collatzStep} \\ \end{array}
```

The collatzSequence is obtained as the output of an automaton with transition function collatzStep, which directly implements the rules given before.

3.2 Coalgebras in general

We work in the category of types A: Set and functions $f: A \to B$. Assume a functor F, whose functoriality is witnessed by mapF, in Agda written as

```
 \begin{array}{ll} \mathsf{F} & : \; \mathsf{Set} \to \mathsf{Set} \\ \mathsf{mapF} & : \; \forall \{A \; B\} \; (f : A \to B) \to (\mathsf{F} \; A \to \mathsf{F} \; B) \end{array}
```

Of course, mapF has to fulfill the functor laws to qualify as a functoriality witness, namely mapF id = id and mapF $(f \circ g) = \text{mapF} f \circ \text{mapF} g$.

An F-coalgebra consists of a pair (S,t) of a type S of states and a transition function t from a state s:S to ts:FS which typically may be some input or output with a (collection of) successor state(s):

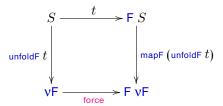

```
S : Set
t : S \rightarrow F S
```

The (weakly) terminal F-coalgebra vF or the coinductive type obtained as the greatest fixed point of F is represented using a coinductive record type in Agda:

```
record vF : Set where force : F vF
```

Here, Agda requires F to be *strictly positive*. Projection force: $vF \rightarrow F vF$ is the *eliminator* of the coalgebra vF. It defines the *observations* one can make on vF. Weak terminality is witnessed by the function unfold $F : S \rightarrow vF$ for any coalgebra (S, t)

which makes the following diagram commute:

Commutation means that the equation of morphisms

$$force \circ unfoldF t = mapF (unfoldF t) \circ t \tag{1}$$

holds. In Agda, we can *implement* unfoldF by taking the pointwise version of Equation (1) as the definition of unfoldF⁴:

```
\{-\# \text{ TERMINATING }\#-\}
unfoldF: \forall \{S\} \ (t:S \to \mathsf{F} \ S) \to (S \to \mathsf{vF})
force (unfoldF t s) = mapF (unfoldF t) (t \ s)
```

4 Interactive programs in Agda

4.1 Interaction interfaces

Interaction of a program with, e.g., an operating system (OS), can be conceived as a sequence of *commands* (elements of Command), given by the program to the OS,

```
\begin{array}{lll} \mathsf{vF} & = & \exists S. \ (S \to \mathsf{F} \, S) \times S \\ \mathsf{unfoldF} \ t & = & \lambda s. \ (t,s) \\ \mathsf{force} & = & \lambda(t,s). \ \mathsf{mapF} \ (\mathsf{unfoldF} \ t) \ (t \, s) \end{array}
```

In contrast to Agda, Matthes' monotone coinductive types do not need strict positivity of F but only the monotonicity witness mapF. Whether this carries over to Agda's predicative type theory needs to be explored. We do not rely on monotone coinductive types, but instead use sized coinductive types to justify the generic unfoldF.

⁴ Digression: In System F with products and (impredicative) existential types, the weakly terminal coalgebra vF is definable (Matthes, 2002) requiring *only* the monotonicity witness mapF:

for each of which the OS sends back a *response* (elements of Response). The type $(R\ c)$ of the response is dependent on the command (c: Command) that was given; thus, in Agda, we model Response as a type family of kind Command \rightarrow Set. The set Command and the indexed set Response form an interface for the interaction (Hancock & Setzer, 2000a). In Agda, this is modeled as a record of sets, and its type lollnterface itself inhabits the next type level Set₁ above Set. Note that lollnterface: Set would require Set: Set, but the latter is inconsistent by Girard's paradox (Girard, 1972; Hurkens, 1995):

```
record IOInterface : Set_1 where Command : Set Response : (c : Command) \rightarrow Set
```

As an example, we define an interface ConsoleInterface of simple console programs. It has only two commands:

```
data ConsoleCommand : Set where
getLine : ConsoleCommand
putStrLn : String → ConsoleCommand
```

The first command, getLine, has no arguments; putStrLn is invoked with one argument of type String:

```
ConsoleResponse : ConsoleCommand \rightarrow Set
ConsoleResponse getLine = Maybe String
ConsoleResponse (putStrLn s) = Unit
```

Upon command getLine, the OS responds with a Maybe String, meaning nothing if the end of input has been reached, and just s when String s could be read from the console. Command (putStrLn s) is always answered with the trivial response Unit, which could be interpreted as success. Together, command and response types form a simple interaction interface:

```
ConsoleInterface : IOInterface

Command ConsoleInterface = ConsoleCommand

Response ConsoleInterface = ConsoleResponse
```

4.2 Interaction trees

From now on, we assume an arbitrary IOInterface

```
I = \text{record} \{ \text{Command} = C; \text{Response} = R \}
```

Let (IO I A) be the type of programs which interact with the interface I and which, in case of termination, return an element of type A. The operations of (IO I A) are

given below. Note that do follows the notation of earlier papers (Hancock & Setzer, 2000a) and is different from Haskell's *do notation*:

The first operation, used in the form do $c \ \lambda r \to fr$, allows us to issue a command c, and continue with fr after receiving the response r:Rc. Note Agda's precedence for λ : We do not have to parenthesize a trailing lambda-abstraction, i.e., do not need to write do $c \ (\lambda r \to fr)$.

The other two operations are desirable so that (IO I) is a monad, i.e., interactive programs can return a result or bind the result a:A of an interactive computation m and continue as another interactive program $(k\,a)$ via $(m\gg \lambda a\to k\,a)$. One can also show that (IO I) fulfils the standard monad laws up to bisimulation.

In principle, an interactive program can issue infinitely many commands. Consider for instance, the program cat which echoes any input through the standard output:

```
cat : IO ConsoleInterface Unit cat = do getLine \lambda{ nothing \rightarrow return unit ; (just \mathit{line}) \rightarrow do (putStrLn \mathit{line}) \lambda \_ \rightarrow cat }
```

In this code snippet, the pattern matching λ expression

```
\lambda{nothing \rightarrow return unit; (just line) \rightarrow \cdots}
```

denotes a function which makes a case distinction on whether the argument is nothing or (just *line*).

The cat program issues the command getLine and terminates when it receives as response nothing, because the end of input has been reached. When it receives (just *line*), it issues the command (putStrLn *line*) and starts over. Potentially, it runs infinitely long. Correspondingly, the IO-tree needs to unfold infinitely deep. Thus, we model IO as a coinductive type (Setzer, 2006):

```
record IO I A: Set where constructor delay force: IO' I A  

data IO' I A: Set where do': (c: Command \ I) (f: Response \ I \ c \to IO \ I \ A) \to IO' \ I \ A return': (a:A) \to IO' \ I \ A
```

The declaration constructor delay is a just convenience that defines a lazy constructor for IO, behaving like the following function:

```
\mathsf{delay'} : \forall \{I \ A\} \to \mathsf{IO'} \ I \ A \to \mathsf{IO} \ I \ A force (\mathsf{delay'} \ x) = x
```

In particular, we cannot match on coinductive constructors (in the same way as we cannot match on defined functions).

With a little force, we define do and return in IO from do' and return' in IO' by copattern matching:

```
\begin{array}{lll} \operatorname{do} & : & \forall \{A\} \; (c:C) \; (f:R \; c \to \operatorname{IO} I \; A) \to \operatorname{IO} I \; A \\ \operatorname{force} \; (\operatorname{do} c \; f) & = & \operatorname{do}' c \; f \\ \\ \operatorname{return} & : & \forall \{A\} \; (a:A) \to \operatorname{IO} I \; A \\ \operatorname{force} \; (\operatorname{return} \; a) & = & \operatorname{return}' \; a \end{array}
```

The monadic bind operation is definable by corecursion, making IO I a monad for each interface I, in the form of Kleisli triple (IO I, return, $_\gg=_$):

The recursive call to $(f \, x \gg = k)$ is justified, as one use of force has been consumed in comparison to the left hand side (force $(m \gg = k)$), and there are only applications of the constructor do' to the right hand side. Therefore, the right hand side requires more applications of force before we need to make a recursive call.

However, the cat program is not strongly normalizing in its present form, since we can unfold its definition recursively arbitrary many times. We need to redefine it using copattern matching, so that at least one application of force is required before having the recursive call. Furthermore, to get it through the termination checker, we need to replace do by do', so that the termination checkers sees that the recursive call is guarded by constructors:

```
\begin{array}{ll} \text{cat}: \text{IO ConsoleInterface Unit} \\ \text{force cat} = \\ \text{do' getLine} & \lambda \{ \text{ nothing} \rightarrow \text{return unit} \; ; \; (\text{just $line$}) \rightarrow \text{delay} \; (\\ \text{do' (putStrLn $line$})} & \lambda \_ \rightarrow \\ \text{cat} & ) \} \end{array}
```

In the latter version, the recursive call to cat in the function body cannot be further rewritten, as only (force cat) reduces. Compare this to the previous version where cat alone already expands, leading to divergence under full reduction.

4.3 Running interactive programs

To run an IO-computation, which unfolds into a potentially infinite command-response tree, we translate it into a NativelO monad, which executes the commands. From the perspective of Agda, the NativelO monad is only axiomatically given by nativeReturn and native \gg =. If, further, we have a function $tr:(c:C)\to \text{NativeIO}(Rc)$ which translates the commands c of a specific interface C into NativeIO-computations of the appropriate response type Rc, we can apply translateIO recursively:

This function is properly NON_TERMINATING, as the translated IO-tree might be infinite. However, this will lead to an infinitely running NativeIO-program, which is the intention. In the above, we used the right-triangle operator $_{\sim}$, representing a flipped function application, as well as anonymous pattern matching in λ -expressions, where the cases are separated by ";":

An example program (using an obvious function translatelOConsole translating console commands into native ones) is as follows:

```
main: NativelO Unit
main = translatelOConsole cat
```

Note that (translatelOConsole cat) is an element of NativelOUnit and therefore already an executable program. One can think of translatelOConsole as a compiler or an interpreter. To some extent we get something which is in between. If the function tr is concretely given, the Haskell compiler can inline it and optimize the resulting instance of translatelO. Therefore, what we get is more than interpretation. However, translatelO does not optimize the given IO-program; therefore, we get less than compilation.

Programs in Agda are translated into Haskell programs using the MAlonzo compiler (Benke, 2007; Agda Wiki, 2011), which are then compiled into executable code. Data types and functions for processing native IO in Agda, including the type NativelO itself, are represented in Agda as postulated types and functions. We use the COMPILED directive of Agda in order to associate corresponding Haskell types and functions with the postulated ones. Especially, NativelO is associated with the

Haskell type IO. MAlonzo will then translate those postulated types and functions into the corresponding Haskell ones. Operations on NativelO are therefore translated into corresponding Haskell operations on IO.

One can consider translateIO as part of the compilation process. Therefore, programs in Agda can be developed without using NON_TERMINATING programs. The use of NON_TERMINATING appears only as an intermediate step during the compilation process.

5 Objects in Agda

As explained in the introduction, the idea of objects in dependent type theory (Setzer, 2006) is that they are server-side interactive programs: An object waits for method calls, then in response to them, returns an answer and changes its state. Changing the state is represented by returning an object with the modified state. Therefore, the interface of an object is given by a set of methods (parametrized over the method arguments) and a set of responses for each method.⁵ In Agda, this is written as

```
 \begin{tabular}{ll} \textbf{record Interface} &: & \textbf{Set}_1 \textbf{ where} \\ \end{tabular}
```

Method : Set

Result : $(m : Method) \rightarrow Set$

Note that Interface and IOInterface are the same except for the names of the eliminators (or observations). A (simple) object for interface I is a coalgebra that has one eliminator objectMethod. For each method of I, objectMethod returns an element of the response type and the new object after the method invocation:

```
record Object (I: Interface) : Set where objectMethod : (m: Method I) \rightarrow Result I m \times Object I
```

An IO object is like a simple object, but the method returns IO applied to the result type of a simple object. In other words, the method returns an IO program for a given IO interface I_{io} , which, if terminating, returns a result of the same type as the corresponding simple object:

```
record IOObject (I_{io}: IOInterface) (I: Interface) : Set where method : (m: Method I) \rightarrow IO I_{io} (Result I m \times IOObject I_{io} I)
```

A class with interface I and instance variables of type A_1, \ldots, A_n corresponds to a function defined coinductively as follows:

```
f: A_1 \to \cdots \to A_n \to Object\ I

objectMethod (f a_1 \cdots a_n) (m b_1 \cdots b_m) = (result, f a_1' \cdots a_n')
```

⁵ This data structure is also known as the type of *containers* (Abbott *et al.*, 2003).

f is the default constructor for this class which creates an object with the instance variables set to its arguments. The object $(f \ a_1 \cdots a_n)$ constructed using f is given by determining the result result of the method call upon invoking its methods, and by determining the updated object. The values $a'_1 \cdots a'_n$ are the content of the instance variables after invoking the method, and the updated object is given by applying the default constructor f to these values.

A constructor for an IO object is defined in the same way as for simple objects, except that on the right-hand side, we have an IO program that returns a value upon termination.

An example is a simple cell of elements of type A. It has two methods: get and (put a) depending on a: A. Method get is intended to return the content of the cell, and has the return type A, and (put a) sets the cell content to a and returns an element of the one element type Unit, which corresponds to void in Java, meaning that no information is returned. The interface in Java is given in Figure 1.

```
interface Cell<A> {
   void put (A s);
   A get ();
}
```

Fig. 1. Cell interface in Java.

In Agda, the cell interface is coded as follows:

```
\begin{array}{lll} \operatorname{data} & \operatorname{CellMethod} A : \operatorname{Set} & \operatorname{where} \\ & \operatorname{get} : \operatorname{CellMethod} A \\ & \operatorname{put} : A \to \operatorname{CellMethod} A \\ \end{array} \begin{array}{lll} \operatorname{CellResult} & : & \forall \{A\} \to \operatorname{CellMethod} A \to \operatorname{Set} \\ \operatorname{CellResult} & \{A\} & \operatorname{get} & = A \\ \operatorname{CellResult} & (\operatorname{put} \_) & = & \operatorname{Unit} \\ \end{array} \begin{array}{lll} \operatorname{CellJ} & : & (A : \operatorname{Set}) \to \operatorname{Interface} \\ \operatorname{Method} & (\operatorname{cellJ} A) & = & \operatorname{CellMethod} A \\ \operatorname{Result} & (\operatorname{cellJ} A) & m & = & \operatorname{CellResult} m \\ \end{array}
```

The cell class is of type IOObject, which has the previously defined ConsoleInterface as an IOInterface and the interface of a cell, w.r.t. String, as object interface:

```
CellC : Set
CellC = IOObject ConsoleInterface (cellJ String)
```

A basic implementation of the cell interface in Java is displayed in Figure 2; the methods log on standard output what is happening—for the sole purpose of demonstrating the IO interface.

```
class SimpleCell<A> implements Cell<A> {
  A content:
  SimpleCell (A s) { content = s; }
 public void put (A s) {
    System.out.println("putting(" + s + ")");
    content = s;
 public A get () {
    System.out.println("getting(" + content + ")");
    return content;
 }
 public static void program () {
    SimpleCell<String> c = new SimpleCell<String>("Start");
    String s = System.console().readLine();
    if (s == null) return; else {
      c.put(s);
      s = c.get();
      System.out.println(s);
      program();
 }
 public static void main (String[] args) {
    program();
  }
}
```

Fig. 2. Simple cell implementation in Java.

In Agda, simple cell objects are constructed by simpleCell, which implements the methods:

```
simpleCell: (s: String) \rightarrow CellC

force (method (simpleCell s) get) =

do' (putStrLn ("getting (" ++ s ++ ")")) \lambda _ \rightarrow

delay (return' (s , simpleCell s))

force (method (simpleCell s) (put x)) =

do' (putStrLn ("putting (" ++ x ++ ")")) \lambda _ \rightarrow

delay (return' (unit , simpleCell x))
```

A test program using simpleCell is defined as follows in Agda. It is very similar to the original Java program, presenting an almost line-to-line translation. The main difference is that in Agda, we have no mutable state; hence, we rely on continuation-passing style with explicit state threading:

The pragma {-# TERMINATING #-} declares program as terminating, overriding the answer from the termination checker. The termination checker says no because on the right hand side of the coinductive definition there is an occurrence of a defined function _>=_ whereas guarded recursion allows only constructors.

In the next section, we will revisit this example using sized typing, and see that with sized types it passes the termination check.

6 Sized coinductive types

In this section, we show how to use sized types to overcome major limitations of the termination checker and enable the user to write modular IO programs.

Sized types have been used for type-based productivity checking of corecursive programs (Hughes *et al.*, 1996; Barthe *et al.*, 2004; Abel & Pientka, 2013; Sacchini, 2013). Section 3 of Igried & Setzer (2016) contains a brief explanation of sized types for coinductive types in Agda. For coinductive types like IO, we should rather speak of *depth* than of size.⁶ The depth is how often one can safely apply force, and the depth of a fully defined coinductive object is ∞ . So, the depth determines how deep we can expect an element by using force. During the (co)recursive definition of an object, we want to speak of depths less than infinity, to verify that on the way to the recursive calls, the depth has increased by at least one. This ensures that the depth grows for each unfolding of recursion, becoming ∞ in the limit.

First, let us define a sized version of the generic weakly terminal coalgebra vF from Section 3. We can then fulfill our promise and justify the generic coiteration operation unfoldF from the monotonicity witness mapF:

The term Size is more suitable for inductive types which are inhabited by trees. There, the size tracked in the type is an upper bound on the height of the tree, or how often one has to apply the constructors in order to obtain that tree. In recursive calls, the height should go down, guaranteeing termination. Note that for infinitely branching trees, the height might be transfinite, so semantically sizes correspond to ordinals rather than to natural numbers. For the use with coinductive types, sizes up to ω , which we call ∞ in our syntax, suffice.

```
record vF (i: Size): Set where constructor delay force: \forall (j: \text{Size} < i) \rightarrow \text{F} (\text{vF } j)
```

The quantification over j: Sizei is reminiscent of the approximation of the greatest fixpoint by deflationary iteration (Sprenger & Dam, 2003; Abel, 2012; Abel & Pientka, 2013). The approximant $\nu^i F$ is defined by induction on ordinal i as follows:

$$\nu^{i} F = \bigcap_{j < i} F(\nu^{j} F)$$

The fact that $\nu^i F$ is monotonically decreasing in i follows directly from the use of intersection $\bigcap_{j < i}$ and is independent of the monotonicity of F. Agda still asks for strict positivity of F, which anyway holds for the common coinductive types. Furthermore, the monotonicity of F gives us the isomorphisms $\nu^{i+1}F = F(\nu^i F)$ and $\nu^\infty F = F(\nu^\infty F)$, mediated by force and delay.

The coiterator unfold F can likewise be defined by induction on i, again by copattern matching:

```
unfoldF: \forall \{S\} (t: S \to F S) \to \forall i \to (S \to \nu F i) force (unfoldF t i s) j = mapF (unfoldF t j) (t s)
```

The type of force guarantees j < i; thus, the recursive call (unfoldF tj) is justified. It gives us a function of type $S \to vFj$ which we map over the application (ts): FS to obtain the right hand side of the required type (F (vFj)). Note how the type of mapF ensures that a result having the required depth j is returned. In particular, mapF cannot involve uses of force, which would necessarily tamper with the depth annotation of vF.

In the sized version of IO, applying force to an IO-tree yields a function that expects a size j < i and then yields an IO'-node, which can be either a do' or a return'. The latter is a leaf, and the former a node consisting of a command c and a (Response c)-indexed collection f of subtrees of that depth:

```
record IO (I_{io}: \mathsf{IOInterface}) (i: \mathsf{Size}) (A: \mathsf{Set}): \mathsf{Set} where constructor delay force : \{j: \mathsf{Size} < i\} \to \mathsf{IO}' \ I_{io} \ j \ A \mathsf{data} \ \mathsf{IO}' \ (I_{io}: \mathsf{IOInterface}) \ (i: \mathsf{Size}) \ \ (A: \mathsf{Set}): \mathsf{Set} \ \mathsf{where} \mathsf{do}' \qquad : \ (c: \mathsf{Command} \ I_{io}) \ \ (f: \mathsf{Response} \ I_{io} \ c \to \mathsf{IO} \ I_{io} \ i \ A) \ \to \mathsf{IO}' \ I_{io} \ i \ A \mathsf{return}': \ \ (a: A) \qquad \to \mathsf{IO}' \ I_{io} \ i \ A
```

⁷ force (delay t) = t holds definitionally in Agda; delay (force t) $\cong t$ holds up to bisimilarity.

Again, this sized coinductive type is justified by deflationary iteration $\nu^i F = \bigcap_{j < i} F(\nu^j F)$. In this case, the *i*th approximant $\nu^i F$ of the greatest fixed point of F would be (IO I_{io} i A) for some fixed I_{io} and A. The type transformation F would be IO' in dependence of (IO I_{io} i A). We can make the correspondence obvious by using nested recursion instead of mutual recursion:

```
data F (X : Set) : Set where do' : (c : Command \ I_{io}) \ (f : Response \ I_{io} \ c \to X) \to F \ X return' : (a : A) \to F \ X record vF (i : Size) : Set where constructor delay force : \{j : Size < i\} \to F \ (vF \ j)
```

Sizes in types allow us to track the guardedness level of expressions independent of their exact formulation. In particular, we can express the guardedness level of a function applied to arguments in terms of the guardedness level of the arguments, rather than having to assume that the function application is unguarded. With the same implementations as for the unsized versions, we obtain the following sized typings for do, return, and _>=_.

The typings of do and $_\gg$ __ express that these functions are guardedness-preserving, meaning that the output is (at least) as guarded as the least guarded input. The type of return simply expresses that we can assume any guardedness for (return a). With subtyping, an equivalent type would be $\forall \{i \ A\}(a:A) \to \mathsf{IO}\ I_{io} \otimes A$, using the covariance $\mathsf{IO}\ I_{io} \otimes A \leqslant \mathsf{IO}\ I_{io}\ i\ A$ of the coinductive type $\mathsf{IO}\$ in its size argument $i \leqslant \infty$.

To understand why the above typing is valid for _>=_, we cast another glance at its implementation. We have made the sizes explicit to see what is going on; however, they can be inserted by Agda automatically. Unfortunately, to supply implicit arguments to an infix operator like _>=_, we have to fall back to prefix notation:

```
force (_>=_ {i} m k) {j} with force m {j} ... | do' c f = do' c \lambda r \rightarrow _>=_ {j} (f r) k ... | return' a = force (k a) {j}
```

The call = = $\{i\}$ m k constitutes an IO-tree of depth i which is defined by the effect of its only elimination form force. Assuming we force it, obtaining a size j < i, we are obliged to produce an IO'-node of size j. We do this by forcing the first given

tree, m, of depth i, by virtue of our size j < i. 8 We proceed by case-distinction on the resulting IO'-node. If it is (do'cf), we execute command c and, after binding the response to r, continue with a recursive call $(fr) \gg k$ at depth j, which is strictly smaller than the depth we started with. Thus, the recursive call is justified. If it is (return'a), we continue with IO-tree (ka) of size i, which we have to force to produce the desired IO'-node of size j.

For an IOObject, the notion of depth is how often we can apply one of its methods. The result of applying a method to an IOObject of depth i is an unbounded IO-tree (depth ∞). Its leaves contain the result of the method call and an IOObject of depth j < i resembling the new state of this object after the method call (and the IO-actions):

```
record IOObject (I_{io}: \mathsf{IOInterface}) (I: \mathsf{Interface}) (i: \mathsf{Size}): \mathsf{Set} where method : \ \forall \{j: \mathsf{Size} < i\} \ (m: \mathsf{Method}\ I) \to \mathsf{IO}\ I_{io} \propto (\mathsf{Result}\ I\ m \times \mathsf{IOObject}\ I_{io}\ I\ j)
```

Sized types already allow us to write the simpleCell constructor slightly more elegantly, using the defined return instead of the combination of delay and return'. Putting the recursive call to simpleCell under the function return is possible due to the polymorphic typing of return : $A \to IOI_{io} \propto A$ which we use with type $A = String \times CellC j$:

```
CellC: (i: \text{Size}) \rightarrow \text{Set}
CellC: = \text{IOObject ConsoleInterface (cellJ String)}

simpleCell: \forall \{i\} \ (s: \text{String}) \rightarrow \text{CellC } i

force (method (simpleCell \{i\} \ s\} \ \{j\} \ \text{get}) =

do' (putStrLn ("getting (" + s ++ ")")) \lambda _- \rightarrow

return (s, simpleCell \{j\} \ s\})

force (method (simpleCell _-) (put s)) =

do' (putStrLn ("putting (" + s ++ ")")) \lambda _- \rightarrow

return (unit, simpleCell s)
```

The program using simpleCell from Section 5 now passes the termination check without modification to its definition. Only its type needs to be refined to exhibit the depth i that will grow with each unfolding of the recursion:

At this point, it is important to note that, if we had no size j < i, we could not force it, or at least not discriminate on the results of forcing it. In particular, if i = 0, then there is no size < i. However, when we have successfully forced $m \gg = k$, meaning that the latter actually evaluated to a delayed node, we know its depth is not 0, and thus there exists a size j < i.

```
\begin{array}{lll} \operatorname{program}: \forall \{i\} \rightarrow \operatorname{IO} \ \operatorname{ConsoleInterface} \ i \ \operatorname{Unit} \\ \operatorname{force} \ \operatorname{program} = \\ & \operatorname{let} \ c_1 = \operatorname{simpleCell} \ "\mathsf{Start"} \ \operatorname{in} \\ & \operatorname{do'} \ \operatorname{getLine} \qquad \lambda \{ \ \operatorname{nothing} \rightarrow \operatorname{return} \ \operatorname{unit}; \ (\operatorname{just} \ s) \rightarrow \\ & \operatorname{method} \ c_1 \ (\operatorname{put} \ s) \ \gg = \lambda \{ \ (\_, \ c_2) \rightarrow \\ & \operatorname{method} \ c_2 \ \operatorname{get} & \gg = \lambda \{ \ (s' \ , \ c_3) \rightarrow \\ & \operatorname{do} \ (\operatorname{putStrLn} \ s') \qquad \lambda \ \_ \rightarrow \\ & \operatorname{program} \ \} \} \} \end{array}
```

Both do and _>=_ preserve the guardedness of the recursive call to program, and this is communicated through the type system.

7 Interface extension and delegation

So far we have shown the implementation in Agda for a single object. In this section, we will show the facets of having several objects and we implement reuse mechanisms based on delegation.

For the purpose of illustration, we introduce the CounterCell class. It extends the functionality of a SimpleCell and counts the number of times an element is stored and retrieved. Further, it includes a method stats to print these statistics. Figure 3 depicts the extended interface in Java.

```
interface StatsCell<A> extends Cell<A> {
    void stats();
}
```

Fig. 3. StatsCell interface in Java.

In Agda, CounterMethod extends the method definition of a SimpleCell, where super lifts a CellMethod of SimpleCell; further, a constructor for the stats method is added:

```
data CounterMethod A: Set where super: (m: CellMethod A) \rightarrow CounterMethod A stats: CounterMethod A
```

Instead of embedding the superclass interface CellMethod into CounterMethod, we could have reused get and put as constructors for CounterMethod, as Agda supports constructor overloading. However, embedding with super gives us benefits later. We can still get nice names for the inherited methods (c indicates a CellMethod) by using Agda's pattern synonym facility:

```
pattern get<sup>c</sup> = super get
pattern put<sup>c</sup> x = super (put x)
```

The full object Interface in Agda is given by statsCelll, in which the result types for put and get refer to SimpleCell and Unit represents void:

Figure 4 shows the CounterCell in Java that is equivalent to our implementation in Agda. Notably, we restrict the implementation to delegation as reuse mechanism as we cannot fully express the subtype relationship between CounterCell and SimpleCell. In particular, the Agda code explicitly states that put and get are defined in the interface of SimpleCell; if we moved the methods to a super class of SimpleCell, we have to adapt our code. In Java, we can override any method without the need to specify in which particular superclass the method is defined in.

In Agda, the class CounterC is defined as a console object

```
CounterC : (i : Size) \rightarrow Set
CounterC = IOObject ConsoleInterface (statsCellI String)
```

The constructor counterCell specifies the functionality of the CounterCell class. The local state includes an object of class CounterC (the class of a SimpleCell) and two natural numbers for the get and put statistics. Each method may issue IO commands or call methods of other objects; get^c and put^c delegate to the respective methods in SimpleCell and return an object with the increased counter variable, whereas stats issues printing of the statistics as an IO command.

```
class CounterCell<A> implements StatsCell<A> {
 Cell<A> cell;
 int ngets, nputs;
 CounterCell (Cell<A> c, int g, int p) {
   cell = c;
   ngets = g;
   nputs = p;
 public A get() {
   ngets++;
   return cell.get();
 public void put (A s) {
   nputs++;
   cell.put(s);
 public void stats() {
   System.out.println ("Counted "
     + ngets + " calls to get and "
      + nputs + " calls to put.");
 }
 public static void program (String arg) {
   CounterCell<String> c = new CounterCell(new SimpleCell("Start"), 0, 0);
   String s = c.get();
   System.out.println(s);
   c.put(arg);
   s = c.get();
   System.out.println(s);
   c.put("Over!");
   c.stats();
   return;
 public static void main (String[] args) {
   program ("Hello");
 }
}
```

Fig. 4. CounterCell implementation in Java.

Finally, the test program is a one-to-one translation from the Java original. This time, it is not recursive, so we do not have to worry about termination:

```
program : String \rightarrow IO ConsoleInterface \infty Unit program arg = let c_0 = \text{counterCell (simpleCell "Start") 0 0 in}
```

```
\gg = \lambda \{ (s_1, c_1) \rightarrow
    method c_0 get<sup>c</sup>
                                             \lambda \longrightarrow
    do (putStrLn s)
                                              \gg = \lambda \{ (\_, c_2) \rightarrow
    method c_1 (put<sup>c</sup> arg)
                                             \gg = \lambda \{ (s', c_3) \rightarrow
    method c_2 get<sup>c</sup>
                                             \lambda \ \_ \to
    do (putStrLn s')
    method c_3 (put<sup>c</sup> "Over!") \gg = \lambda \{ (_-, c_4) \rightarrow
    method c<sub>4</sub> stats
                                              \gg = \lambda \{ (c_1, c_5) \rightarrow
                                              }}}}
    return unit
main: NativelO Unit
main = translateIO translateIOConsoleLocal (program "Hello")
```

8 State-dependent objects and IO

8.1 State-dependent interfaces

We motivate stateful object interfaces with the implementation of a stack. A stack has two operations: push places an object on the stack, and pop removes the top object and returns it. Consider a stack interface in Java:

```
public interface Stack<E> {
  void push(E e);

  /** @throws EmptyStackException if the stack is empty **/
  E pop() throws java.util.EmptyStackException;
}
```

A stack underflow happens when the pop method is called on an empty stack. In the Java Development Kit (JDK), the pop method throws a runtime exception, which the programmer is advised but not forced to catch.

In Agda, a safer version of a stack class can be defined, where the type system ensures that a pop operation may only be performed on a non-empty stack. The interface depends on the state of the stack, i.e., the number of elements that are on the stack:

```
StackState^s = N
```

A state-dependent object interface in Agda⁹ is given by a value of the following record type (superscript ^s indicates the state-dependency of the interface):

```
record Interface<sup>s</sup>: Set<sub>1</sub> where
State<sup>s</sup>: Set
Method<sup>s</sup>: (s: State^s) \rightarrow Set
Result<sup>s</sup>: (s: State^s) \rightarrow (m: Method^s s) \rightarrow Set
next<sup>s</sup>: (s: State^s) \rightarrow (m: Method^s s) \rightarrow (r: Result^s s m) \rightarrow State^s
```

⁹ Also known as indexed container (Altenkirch & Morris, 2009).

The set of methods depends on the state of the object, while the result depends on the state and the invoked method. The next^s function determines the successive state after the result of the method invocation has been computed.

To model state-dependent methods, StackMethod^s needs to be indexed by the size of the stack. The pop method is only available when the size is non-zero, i.e., of the form $suc\ n$ (successor of some natural number n). In Agda, this is realized by an indexed data type, aka inductive family (Dybjer, 1994):

```
data StackMethod<sup>s</sup> (A: Set): (n: StackState^s) \rightarrow Set where push : \forall \{n\} \rightarrow A \rightarrow StackMethod^s A n pop : \forall \{n\} \rightarrow StackMethod^s A (suc n)
```

Pushing to a stack has no return value (Unit), whereas the result of popping from a stack of As is an element of type A:

```
 \begin{array}{lll} {\sf StackResult^s} & : & (A:{\sf Set}) \to (s:{\sf StackState^s}) \to {\sf StackMethod^s} \; A \; s \to {\sf Set} \\ {\sf StackResult^s} \; A \; \_ \; \; ({\sf push} \; \_) & = \; \; {\sf Unit} \\ {\sf StackResult^s} \; A \; \_ \; \; {\sf pop} & = \; A \\ \end{array}
```

The next state after a push operation is a stack with an increased size (i.e., state (suc n)), while pop leads to a decreased size:

The previous definitions allow us to assemble the state-dependent interface for stack objects:

```
\begin{array}{lll} {\sf StackInterface^s:(A:Set)} & \to {\sf Interface^s} \\ {\sf State^s} & ({\sf StackInterface^s} \ A) & = {\sf StackState^s} \\ {\sf Method^s:} & ({\sf StackInterface^s} \ A) & = {\sf StackMethod^s} \ A \\ {\sf Result^s:} & ({\sf StackInterface^s} \ A) & = {\sf StackResult^s} \ A \\ {\sf next^s:} & ({\sf StackInterface^s} \ A) & = {\sf stackNext^s} \ A \\ \end{array}
```

8.2 State-dependent objects

A state-dependent object for interface I is a coalgebra that has one eliminator objectMethod, which for each method of I returns an element of the response type and the adapted object:

```
record Object<sup>s</sup> (I: Interface<sup>s</sup>) (s: State<sup>s</sup> I): Set where objectMethod: (m: Method<sup>s</sup> I s) \rightarrow \Sigma[ r \in \mathsf{Result}^s I \ s \ m] Object<sup>s</sup> I (next<sup>s</sup> I s m r)
```

Since the type of the returned object depends, via next^s, on the returned result r, we need to type the returned pair via a Σ -type, defined in Agda's standard library. Here, Σ [$x \in A$] B denotes Σ A ($\lambda x \to B$), where Σ A C is the dependent product type defined as a record with fields proj₁: A and proj₂: C proj₁. ¹⁰

The state-dependent version of an IO object is

```
record IOObject<sup>s</sup> (I_{io}: IOInterface) (I: Interface<sup>s</sup>) (s: State<sup>s</sup> I): Set where method: (m: Method<sup>s</sup> I s) \rightarrow IO I_{io} \propto (\Sigma[\ r \in \mathsf{Result}^s\ I\ s\ m\ ] IOObject<sup>s</sup> I_{io}\ I\ (\mathsf{next}^s\ I\ s\ m\ r))
```

IOObject^s is a straightforward adaption to state-dependency of IOObject from Section 5. The IO version of a stack object could additionally log its activity on an output channel. However, in the following we restrict it to the non-IO version for clarity of exposition.

The simplest implementation of a stack object is just a wrapper of its data, a stack implemented as a vector (Vec A n) of elements in type A, where n is the current stack size:

```
stack : \forall \{A\}\{n:\mathbb{N}\}\ (as: \mathsf{Vec}\ A\ n) \to \mathsf{Object}^\mathsf{s}\ (\mathsf{StackInterface}^\mathsf{s}\ A)\ n objectMethod (stack as) (push a) = unit , stack (a::as) objectMethod (stack (a::as)) pop = a , stack as
```

In the case of method pop, in principle, we have two cases for the content on the stack: First, the stack is non-empty, i.e., of the form a::as where a is the top element and as is the rest. This case is handled by the second clause. The other case, the stack being empty, i.e., of the form [], is ruled out by the dependent typing: method pop expects n to be a successor, but []: Vec A 0 enforces n=0. This allows Agda to conclude that this case is impossible, and no clause has to be written for it. In contrast with the Java version, no exception handling is needed.

Objects that may flexibly depend on runtime values may not only be suitable for ensuring runtime invariants, but may also help model extensions of object-oriented programming; for instance, method dispatch may depend on another dimension. Consider *context-oriented programming* (Hirschfeld *et al.*, 2008), where the behavior of an object depends on a given execution context that can be activated dynamically at runtime.

Note that Objects is given as a ΠΣ-types rather than ΣΠ-types. In general, polynomial functors can be reduced to ΣΠ-types (see, e.g., Setzer (2016)). The coalgebras corresponding to ΣΠ-functors are Petersson–Synek trees (Petersson & Synek, 1989), which are trees with nodes indexed over some set I, and each node having a label and a branching degree (where the set of labels, the branching degree, and the index set of the subtrees depend on the index of the root). The theory of indexed containers (Hancock et al., 2013) shows that indexed coalgebras of polynomial functors can be reduced to Petersson–Synek trees. Coalgebras given by ΠΣ-types will be essentially Petersson–Synek trees. However, the label is only given to the subtrees of a node, not to a node itself. This amounts to having trees which differ from Petersson–Synek trees by not having a label at the root. By forming a product consisting of the type of ΠΣ-trees and the type of labels at the root, we obtain a tree which is equivalent to a Petersson–Synek tree. Therefore, we obtain the full generality of coalgebras of polynomial functors.

8.2.1 Example of use of safe stack

We consider an example of the use of safe stacks, where type theoretic rules prevent the use of pop on empty stacks.

A stack machine for evaluating the Fibonacci numbers iteratively using a safe stack serves as an illustration. This is essentially the result of computing the recursive definition of the Fibonacci numbers (which is of course inefficient) using a stack. This definition can easily be generalised to other recursive functions. The presented example is an adaption of Section 5.1.4. of Abelson *et al.* (1996).

The stack machine consists of a state, a number $n:\mathbb{N}$, and a stack of size n. The state is either an expression (fib m) to be evaluated or a value (val k) to be returned. The elements of the stack are expressions with a hole \bullet , into which k is to be inserted, once the stack above it has been emptied, and the state has become a value (val k). These elements are of the form (\bullet +fib m), which means that (fib m) has to be added to the result k, or $k' + \bullet$, which means that the result k has to be added to k':

```
data FibState : Set where
fib : \mathbb{N} \to \text{FibState}
val : \mathbb{N} \to \text{FibState}

data FibStackEl : Set where
_{-} + \bullet \quad : \ \mathbb{N} \to \text{FibStackEl}
_{-} + \text{fib}_{-} : \ \mathbb{N} \to \text{FibStackEl}
FibStack : \mathbb{N} \to \text{Set}
FibStack = Object<sup>s</sup> (StackInterface<sup>s</sup> FibStackEl)

FibStackmachine : Set
FibStackmachine : Set
```

The function reduce carries out a one-step reduction, returning either a new stack machine or the value computed, i.e., an element of the disjoint union of the two sets. If the state is (val k), then this expression is used to reduce the top element on the stack. If the state is (fib m), then the machine is supposed to compute (fib m). In case of m = m' + 2 we have (fib (m' + 1)) as the next state, which when evaluated will be inserted into the whole of the element (\bullet +fib m') pushed onto the stack, computing fib (m' + 1) + fib m'. Note that we never pop from the stack when it is empty:

Note that we use the previously defined right-triangle operator \triangleright which can be used to make a method call and —depending on the result—continue with a succeeding operation. The function computeFibRec repeatedly applies reduce until it returns a result. We know it is TERMINATING. However, since we did not calculate how often we should iterate this operation, we have to override the termination checker:

fibUsingStack computes the Fibonacci function:

```
fibUsingStack : \mathbb{N} \to \mathbb{N} fibUsingStack m = \mathsf{computeFibRec}\ (0 \ , \ \mathsf{fib}\ m \ , \ \mathsf{stack}\ [])
```

8.3 Reasoning about stateful objects

8.3.1 Bisimilarity

Henceforth, we assume an arbitrary I: Interface^s and use O for the type of objects of this interface. Assume

```
I = \operatorname{record} \{ \operatorname{State}^{\operatorname{s}} = S; \operatorname{Method}^{\operatorname{s}} = M; \operatorname{Result}^{\operatorname{s}} = R; \operatorname{next}^{\operatorname{s}} = \operatorname{next} \} 
O = \operatorname{Object}^{\operatorname{s}} I
```

In Agda, the equality used in type checking is definitional equality, which is a decidable equality based on equality of normal forms up to α , η -equality. It is not extensional. For instance, functions are equal if they have the same normal form, not if they return equal values for equal arguments. The standard generic propositional equality in Agda is Martin-Löf's intensional equality type. One can define extensional propositional equality types, but the preservation of such equalities by functions needs to be proved for each instance needed.

The natural extensional equality on coalgebras is bisimilarity, which means that two elements of coalgebras are *bisimilar* if all eliminators return equal or bisimilar results for equal arguments. Since the result type of an eliminator might refer to the coalgebra, this results in a recursive definition. Because the coalgebra is defined coinductively, it is natural to define the bisimilarity coinductively as well. Essentially, this means that two elements of a coalgebra are bisimilar, if, after repeatedly applying eliminators until one obtains an element of a type which was defined before the coalgebra was introduced, one obtains equal results. Adapted to objects, this means that two objects are *bisimilar* if they yield the same responses if subjected to the same method calls, which is a recursive definition to be understood coinductively.

To express bisimilarity in Agda, let us first define a relation ΣR R on dependent pairs $(a,b),(a',b') \in \Sigma$ A B that holds iff the first components $a,a' \in A$ are identical and the second components $b,b' \in B$ a are related by R $a:(b\ b':B\ a) \to \operatorname{Set}^{11}$:

```
data \Sigma R \{A: \mathsf{Set}\}\ \{B: A \to \mathsf{Set}\}\ (R: \forall \{a\}\ (b\ b': B\ a) \to \mathsf{Set}\}
: (p\ p': \Sigma[\ a \in A\ ]\ B\ a) \to \mathsf{Set}
where
\mathsf{eq}\Sigma: \ \forall \{a\}\{b\ b': B\ a\} \to R\ b\ b' \to \Sigma R\ R\ (a\ ,\ b)\ (a\ ,\ b')
```

We can establish ΣR R (a,b) (a,b') using constructor eq Σ , provided we have a proof of (R b b'). This enables us to define the bisimilarity relation coinductively in a very similar way to how we have defined objects:

```
record \_\cong \_\{s:S\}\ (o\ o':O\ s): Set where bisimMethod : (m:M\ s)\to \Sigma R\ (\_\cong \_)\ (objectMethod\ o\ m)\ (objectMethod\ o'\ m)
```

A bisimilarity derivation $o \cong o'$ for two objects $o, o' \in Os$ at the same state s is an infinite proof tree which we can, by bisimMethod, query for its node sitting on branch m: Ms for a valid method call m. This node will consist of an eq Σ constructor certifying the identity of responses and holding a subtree for the equality of the objects after the method invocation.

Reflexivity of bisimilarity is shown corecursively; the proof, as the statement, is rather trivial.

```
refl\cong: \forall \{s\} \ (o:O\ s) \to o \cong o
bisimMethod (refl\cong o) m= let (r\ ,o')= objectMethod o\ m
in eq\Sigma (refl\cong o')
```

To show that o is bisimilar to itself, we subject it to an arbitrary method call m. Trivially, there is only one result r, which is equal to itself. By the coinduction

¹¹ SR is an example of an inductive family, which are special cases of inductive–recursive definitions. See Dybjer & Setzer (2003) for a model of inductive–recursive definitions.

hypothesis, the new object o' is bisimilar to itself, thus, eq Σ is sufficient to establish bisimilarity.

```
8.3.2 Verifying stack laws
```

In this section, we show that two stack laws hold for our implementation of a stack by a vector. Both hold in Agda by computation, so reflexivity of bisimilarity is sufficient to prove them.

The first law states that for an arbitrary stack st constructed from a vector v of elements of type E, if we first push an arbitrary element e and then pop from the stack, we get back e and the original stack:

```
\begin{array}{lll} \mathsf{pop-after-push} : \forall \{n\} \; \{v : \mathsf{Vec} \; E \; n\} \; \{e : E\} \rightarrow \\ & \mathsf{let} \; \; st & = \; \mathsf{stack} \; v \\ & (\_, \; st_1) \; = \; \mathsf{objectMethod} \; \; st \; \; (\mathsf{push} \; e) \\ & (e_2 \; , \; st_2) \; = \; \mathsf{objectMethod} \; \; st_1 \; \; \mathsf{pop} \\ & \mathsf{in} \; \; (e \equiv e_2) \times (st \cong st_2) \\ & \mathsf{pop-after-push} = \mathsf{refl} \; , \; \mathsf{refl} \cong \_ \end{array}
```

In Agda, the proof is trivial by expansion of the definition of our stack implementation: first, st_1 computes to stack (e :: v), then the pair (e_2, st_2) computes to (e, stack v), and both goals hold by reflexivity.

The second law concerns the opposite order of these operations. If we first pop and element from stack st constructed from the non-empty vector e::v, and then push the popped element, we end up with the same stack st:

```
push-after-pop: \forall \{n\} \ \{v : \text{Vec } E \ n\} \ \{e : E\} \rightarrow
let st = \text{stack } (e :: v)
(e_1 \ , \ st_1) = \text{objectMethod } st \text{ pop}
(\_ \ , \ st_2) = \text{objectMethod } st_1 \text{ (push } e_1)
in st \cong st_2
push-after-pop = refl\cong _
```

Again, this lemma is proven by computation.

```
8.3.3 Bisimilarity of different stack implementations
```

Alternatively to a vector, we can store the stack contents in a finite map implemented naively as a pair of a number $n : \mathbb{N}$, which denotes the stack size, and a function $f : \mathbb{N} \to E$, which gives direct access to the stack elements, with f 0 standing for the top element and f (n-1) for the bottom element. The value of f k for $k \ge n$ is

irrelevant. We can transform such a finite map into a vector through the function (tabulate n f), which computes the vector f 0 :: f 1 :: · · · :: f (n-1) :: [] and will be used to relate the finite maps and vectors later:

```
tabulate : \forall (n:\mathbb{N}) (f:\mathbb{N}\to E)\to \mathrm{Vec}\;E\;n tabulate 0 f=[] tabulate (suc n) f=f0 :: tabulate n (f\circ\mathrm{suc})
```

The object stack F f implements a stack represented by the finite map (n, f). Pushing a new element e onto the stack will result in increasing the stack size to (suc n) and changing the function f to a new function f' such that top position 0 maps to the new element e and position m+1 maps to (f m). Basically, we have shifted the old stack content to make space for the new element e in position 0^{12} :

```
\begin{array}{lll} \operatorname{stackF}: \forall \; (n:\mathbb{N}) \; (f:\mathbb{N} \to E) \to \operatorname{Object^s} \; (\operatorname{StackInterface^s} \; E) \; n \\ \operatorname{objectMethod} \; \; (\operatorname{stackF} \; n \; & f) \; (\operatorname{push} \; e) = \; \_ \; \; , \; \operatorname{stackF} \; (\operatorname{suc} \; n) \; \lambda \\ \left\{ \begin{array}{ccc} 0 & \to \; e \\ \vdots & (\operatorname{suc} \; m) \; \to \; f \; m \end{array} \right\} \\ \operatorname{objectMethod} \; \; (\operatorname{stackF} \; (\operatorname{suc} \; n) \; \; f) \; \operatorname{pop} & = \; f \; 0 \; \; , \; \operatorname{stackF} \; n \; (f \; \circ \operatorname{suc}) \end{array}
```

Popping from the stack returns the top element f 0 and changes the stack size from (suc n) to n and the representing function from f to $f \circ suc$.

Given a finite map (n, f) that tabulates to a vector v, we obtain bisimilar stack objects (stackF n f) and (stack v). After we push a new element e we can invoke the coinduction hypotheses on the new stack objects provided that their data is still in correspondence, (tabulate (suc n) $f' \equiv (e :: v)$). By definition of tabulate, the heads of these vectors are both e, and the equality of their tails is the assumption p:

```
\begin{split} & \text{impl-bisim}: \, \forall \{n \ f\} \ v \ (p: \text{tabulate} \ n \ f \equiv v) \rightarrow \text{stackF} \ n \ f \cong \text{stack} \ v \\ & \text{bisimMethod} \ (\text{impl-bisim} \ v \qquad p) \ (\text{push} \ e) = \\ & \text{eq} \Sigma \ (\text{impl-bisim} \ (e :: v) \ (\text{cong} \ (\_::\_e) \ p)) \end{split} & \text{bisimMethod} \ (\text{impl-bisim} \ (e :: v) \ p) \ \text{pop rewrite} \ \text{cong head} \ p = \\ & \text{eq} \Sigma \ (\text{impl-bisim} \ v \qquad (\text{cong tail} \quad p)) \end{split}
```

One of the referees suggested considering a different implementation, where one appends elements at the end (at f n) rather than at the beginning (f 0). Popping would then be the result of merely changing the n-value. The problem is that pushing is much more complicated since we cannot define it via pattern matching, but would need an if-then-else statement on whether the argument is equal to n. This is not a problem for defining the function – however, proofs referring to if-then-else statements are much more complicated than proofs referring to pattern matching definitions. Therefore, our solution is more suitable for proving properties.

Here, (cong head p) has type f 0 = e, where f is the implicit argument. The syntax rewrite cong head p makes an implicit case distinction on (cong head p), which in this example equates f 0 with e.¹³

When popping from a non-empty stack whose vector representation is e::v, we first have to show the equality of the result component, $f \ 0 \equiv e$. This equation is obtained from p: tabulate (suc n) $f \equiv (e::v)$ by applying head on both sides. After rewriting with this equation, we can proceed with eq Σ and apply the coinduction hypothesis with tabulate $n(f \circ \text{suc}) \equiv v$, which we get from p by applying tail on both sides.

8.4 State-dependent IO

State-dependent interactive programs are defined in a similar way as state-dependent objects, except for replacing Method^s by Command^s and Result^s by Response^s. Later, we will use state dependent IO in a situation where the components have different type levels (Set vs Set₁). We, therefore, define the operations polymorphically in the finite type levels α , σ , γ , ρ , which from now we consider fixed but arbitrary. Levels have the lowest element Izero, successor operation Isuc and the maximum operation \Box^{14} :

```
record IOInterface<sup>s</sup> : Set (Isuc (\sigma \sqcup \gamma \sqcup \rho)) where State<sup>s</sup> : Set \sigma Command<sup>s</sup> : State<sup>s</sup> \rightarrow Set \gamma Response<sup>s</sup> : (s : State<sup>s</sup>) \rightarrow Command<sup>s</sup> s \rightarrow Set \rho next<sup>s</sup> : (s : State<sup>s</sup>) \rightarrow (c : Command<sup>s</sup> s) \rightarrow Response<sup>s</sup> s c \rightarrow State<sup>s</sup>
```

State-dependent IO programs are defined in a similar way as state-dependent Objects (here, $S=State^s$ i, $C=Command^s$ i, $R=Response^s$ i, $next=next^s$ i):

```
record \mathsf{IO}^s (i:\mathsf{Size}) (A:S\to\mathsf{Set}\;\alpha) (s:S):\mathsf{Set}\;(\mathsf{Isuc}\;(\alpha\sqcup\sigma\sqcup\gamma\sqcup\rho\;)) where constructor delay force<sup>s</sup> : \{j:\mathsf{Size}< i\}\to\mathsf{IO}^{s'}j\;A\;s \mathsf{data}\;\mathsf{IO}^{s'}\;(i:\mathsf{Size})\;(A:S\to\mathsf{Set}\;\alpha):S\to\mathsf{Set}\;(\mathsf{Isuc}\;(\alpha\sqcup\sigma\sqcup\gamma\sqcup\rho\;))\;\mathsf{where}\; \mathsf{do}^{s'}\;\;:\;\{s:S\}\to(c:C\;s)\to(f:(r:R\;s\;c)\to\mathsf{IO}^s\;i\;A\;(next\;s\;c\;r)\;) \to\;\mathsf{IO}^{s'}\;i\;A\;s \mathsf{return}^{s'}\;:\;\{s:S\}\to(a:A\;s)\to\mathsf{IO}^{s'}\;i\;A\;s \mathsf{return}^{s}\;:\;\forall\{i\}\{A:S\to\mathsf{Set}\;\alpha\}\;\{s:S\}\;(a:A\;s)\to\mathsf{IO}^s\;\;I\;i\;A\;s \mathsf{force}^s\;(\mathsf{return}^s\;a)=\mathsf{return}^{s'}\;a
```

¹³ See Agda (2016) on how to reduce the rewrite-construct to the with-construct. The with-construct was introduced in McBride & McKinna (2004).

Note that Set α has type Set (Isuc α) and (α : Level) \rightarrow Set α has type Set ω , which is a universe above any Set α . Universe Set ω only exists internally in Agda as the type of level-polymorphic universes, it cannot be written by the user. It is needed in type theoretic rules which require to associate a type for any A occurring in a typing judgment a:A.

```
\begin{array}{ll} \mathsf{do^s} \ : \ \forall \{i\}\{A:S \to \mathsf{Set}\ \alpha\}\ \{s:S\} \\ & (c:C\ s)\ (f:(r:R\ s\ c) \to \mathsf{IO^s}\ I\ i\ A\ (next\ s\ c\ r)) \to \mathsf{IO^s}\ I\ i\ A\ s \\ & \mathsf{force^s}\ (\mathsf{do^s}\ c\ f) = \mathsf{do^{s'}}\ c\ f \end{array}
```

Translation into NativelO is as before; however, the type level ρ of Responses has to be Izero. Furthermore, the result type needs to be independent of s and in Set:

```
 \begin{array}{l} {\sf translatelO^s}: \, \forall \{A: {\sf Set} \, \} \{s: S\} \\ \rightarrow \  \, ({\it translateLocal}: (s: S) \rightarrow (c: C \, s) \rightarrow {\sf NativelO} \, (R \, s \, c)) \\ \rightarrow \  \, {\sf IO^s} \, \, I \propto (\lambda \, s \rightarrow A) \, \, s \\ \rightarrow \  \, {\sf NativelO} \, \, A \\ \end{array}
```

9 A drawing program in Agda

In this section, we will introduce a graphics library in Agda and implement a proof-of-concept drawing program with it. The library is using Hudak's SOE Haskell library (Hudak, 2016). The GUI interface in the Agda library has commands for creating, changing, and closing GUI components, and for checking for GUI events such as pressed keys (together with the character pressed) or mouse movements (together with the new point). The library will refer to data types representing GUI-related data such as a type Window of windows. All these commands and types will be translated to Haskell functions and types using the SOE library:

```
data GraphicsCommands: Set where
  getWindowEvent : Window → GraphicsCommands
  openWindow : String \rightarrow Maybe Point \rightarrow \mathbb{N} \rightarrow \mathbb{N}
                              → RedrawMode → Maybe Word32
                              → GraphicsCommands
                   : Window \rightarrow GraphicsCommands
  closeWindow
  drawInWindow
                   : Window \rightarrow Graphic \rightarrow GraphicsCommands
GraphicsResponses: GraphicsCommands → Set
GraphicsResponses (getWindowEvent _)
                                          = Event
GraphicsResponses (openWindow _ _ _ _ _ ) = Window
GraphicsResponses (closeWindow _)
                                              = Unit
GraphicsResponses (drawInWindow _ _)
                                               = Unit
GraphicsInterface
                                 IOInterface
Command GraphicsInterface = GraphicsCommands
Response GraphicsInterface = GraphicsResponses
\mathsf{IOGraphics}: \mathsf{Size} \to \mathsf{Set} \to \mathsf{Set}
IOGraphics i = IO GraphicsInterface i
```

Graphics commands are translated into native IO commands by a function translateNative, which replaces each command by a native function:

```
translateNative : (c : GraphicsCommands) \rightarrow NativelO (GraphicsResponses <math>c)
```

We define now a simple drawing program, which opens a window and draws a trace of where the mouse moves. After having started, the state of the program is given by the last point up to which the drawing has already been carried out. After the first mouse movement event at point p, the drawing consists of a single point at position p. Initially there is no such point. So, we define the state as

```
State = Maybe Point
```

The loop of the program checks for any window event, which are handled by winEvtHandler. If key 'x', representing a request to terminate the program, was pressed, the program closes the window and terminates. If, after we have started (state (just p_1)), a mouse movement event with point p_2 occurs, a line is drawn from p_1 to p_2 , and the state is updated to (just p_2). If the same mouse movement event occurs in the initial state nothing, no line is drawn, but as before the state is updated to (just p_2). In all other cases, winEvtHandler calls the loop function without changing the state:

```
mutual
                           : \forall \{i\} \rightarrow \mathsf{Window} \rightarrow \mathsf{State} \rightarrow \mathsf{IOGraphics}\ i\ \mathsf{Unit}
   loop
   force (loop w s) = do' (getWindowEvent w) \lambda e \rightarrow
                                winEvtHandler w s e
   winEvtHandler : \forall \{i\} \rightarrow \text{Window} \rightarrow \text{State} \rightarrow \text{Event} \rightarrow \text{IOGraphics } i \text{ Unit}
   winEvtHandler w s (Key c t)
                                                      = if charEquality c 'x'
                                                            then (do (closeWindow w) return)
                                                            else loop w s
   winEvtHandler w s (MouseMove p_2) = s \triangleright \lambda
       { nothing \rightarrow loop w (just p_2)
       ; (just p_1) \rightarrow do (drawlnWindow w (line p_1 p_2)) \lambda \rightarrow
                            loop w (just p_2) }
                                                       = loop w s
   winEvtHandler w s _
```

The main program opens a window and then runs the loop. This program is then translated into a native IO program:

```
program : \forall \{i\} \rightarrow \text{IOGraphics } i \text{ Unit} program = do (openWindow "Drawing Prog" nothing 1000 1000 nativeDrawGraphic nothing) \lambda \ win \rightarrow \text{Ioop } win \text{ nothing}
```

 $translate IO Graphics: IO Graphics \\ \infty \ Unit \\ \rightarrow \ Native IO \ Unit \\ translate IO Graphics \\ = translate IO \ translate Native$

main: NativelO Unit

main = nativeRunGraphics (translateIOGraphics program)

10 A graphical user interface using an object

10.1 Graphical user interfaces with event handlers

So far our interactive programs were client-side programs: The program issues commands and receives responses. In the drawing program in Section 9, we ran a loop that was checking for any events that had occurred and modified the program state accordingly. When dealing with more complex GUIs this becomes inefficient. A better way is to use event listeners.

In object-oriented programming languages such as Java, when creating a GUI, one uses commands which create GUI elements such as frames, buttons, and text fields, and commands for placing them usually within previously created GUI elements. For instance, one can place a button within a frame.

These GUI elements are associated with events, which are usually triggered by user interaction. For example, once we have created a button, a button click event is created, which is activated whenever the button is pressed. Moreover, there are events triggered by the user interface itself, such as the paint event that signals that a window's contents needs to be repainted. Events are handled by event listeners or event handlers. An event handler is an interactive program that is executed whenever the event is triggered and is provided with parameters accordingly. For instance, when a mouse click event is triggered, one obtains the coordinates of the location of the mouse click. An event handler also has other parameters which are implicit, such as the device context. When the event is triggered, the event handler is applied to these arguments.

In object-oriented programming such as Java, the event handlers are usually invoked as methods of several objects. This allows communication between the event handlers. In Section 10.2, we will introduce an example of a spaceship controlled by a button. The coordinates of the spaceship are changed when a button is pressed. The paint event handler then uses these coordinates to draw the spaceship at a different location.

10.2 wxHaskell

In this section, we will translate our IO programs into native IO programs, which then translate into Haskell programs by making use of the Haskell library wxHaskell (Leijen, 2004; Haskell Wiki, 2016). This library is suitable for creating GUIs since it has good support for server-side programs based on action handlers. Here, "server-side" refers to the notion put forth by Hancock & Setzer (2005) and Setzer & Hancock (2004). The wxHaskell library offers bindings for wxWidgets, and an

object-oriented (C++) widget toolkit to build GUIs. For each method in C++ there is a wrapper function in C with a pointer to a struct representing an object. The Haskell library binds to the C functions. As the C++ methods assume access to a mutable state, wxHaskell makes use of mutable variables. Our examples use mutable variables based on Concurrent Haskell (Peyton Jones *et al.*, 1996). In our Agda code, we do not focus on modeling the inheritance relationship between widgets that is present in the C++ library. In wxHaskell, inheritance relationships are modeled as phantom types; however, as it relies on unsafe object casts, it is only an approximation that does not fully represent subtyping of object-oriented programming languages (see the related work of phantom types in Section 11).

wxHaskell provides some basic data types such as the device context DC, frame Frame and button Button. Additionally, it provides functions for creating and placing GUI elements. GUI elements have properties, using syntax such as

```
frame [text := "Frame Title"]
```

for creating a frame with the title "Frame Title." Event handlers are associated with GUI elements by using syntax such as

```
set myframe [on paint := prog]
```

which sets the onpaint method (in underlying C++ terms) for frame myframe to program prog, where prog is an element of IO () in Haskell. In order to share information between event handlers, mutable variables are used. As multiple events may occur in parallel, we use variables based on Concurrent Haskell (Peyton Jones et al., 1996):

A mutable location MVar a is either empty or contains a value. There are commands for creating a mutable location, putting a value into the location, and taking a value out of the location:

```
newMVar :: a -> IO (MVar a)
putMVar :: MVar a -> a -> IO ()
takeMVar :: MVar a -> IO a
```

A thread putting a variable blocks until the variable is empty, and then puts a value into that location. If it is taking a variable, it blocks until the variable is non-empty, and then reads the value, leaving the location empty. The dispatch function in the next section utilizes Haskell's MVar semantics to implement thread-safe communication. The Agda Var type corresponds to the Haskell MVar type and, e.g., nativePutVar is a wrapper for putMVar in Haskell.

10.3 A library for object-based GUIs in Agda

We will handle variables by forming a list of variables. Since a variable depends on its type—an element of Set—a list of variables is an element of the next type level

Set₁ above Set:

```
data VarList : Set<sub>1</sub> where
[] : VarList
addVar : (A : Set) \rightarrow Var A \rightarrow VarList \rightarrow VarList
```

We form the product of the set of variables in a VarList. In our example below, we have only one variable of type A. In order to obtain it as product A instead of $A \times \text{Unit}$, we add a special case for the singleton list:

```
\begin{array}{lll} \operatorname{prod}: \operatorname{VarList} \to \operatorname{Set} \\ \operatorname{prod} & [] & = \operatorname{Unit} \\ \operatorname{prod} & (\operatorname{addVar} A \ v \ []) & = A \\ \operatorname{prod} & (\operatorname{addVar} A \ v \ l) & = A \times \operatorname{prod} \ l \end{array}
```

The function takeVar reads in sequence all the variables, empties them, and returns the product. If a variable is empty, it waits until it is non-empty, before taking it. The function putVar writes all the variables, leaving them non-empty. If a variable is non-empty, it waits until it is empty, before putting the value:

```
takeVar : (l : VarList) \rightarrow NativelO (prod l)
takeVar []
                                            = nativeReturn unit
takeVar (addVar A v [])
                                           = nativeTakeVar \{A\} v
takeVar (addVar A v (addVar B v' l)) =
   nativeTakeVar \{A\} v
                               native \gg = \lambda \ a \rightarrow
   takeVar (addVar B v' l) native\gg = \lambda rest \rightarrow
   nativeReturn ( a , rest )
putVar : (l : VarList) \rightarrow prod l \rightarrow NativelO Unit
putVar []_
                                                     = nativeReturn unit
putVar (addVar A v []) a
                                                     = nativePutVar \{A\} v a
putVar (addVar A v (addVar B v' l) (a, rest) =
   nativePutVar \{A\} v a native\gg = \lambda \rightarrow
   putVar (addVar B v' l) rest
```

We have two levels of IO interfaces: the level 1 interface GuiLev1Interface is used for creating and modifying GUI elements without making use of event handlers. It does not, however, allow the use of variables. We omit its definition, which is similar to the one given in Section 9.

The main program uses the level 2 interface, which extends the level 1 interface and has commands for adding event handlers that refer to programs written for the level 1 interface. This means that it *negatively* refers to the set of all level 1 IO programs. In order for this to be possible, the set of level 1 programs needs to be defined (and therefore the level 1 interface be finished) before we can define the level 2 interface. If we allowed the level 2 interface to refer to itself we would

get an *inconsistent type theory* (essentially, we would need the principle Set : Set). Therefore, we could not use Agda for verification.

Because of this, we separate level 1 and level 2 interfaces: The level 1 interface has no event handler. The level 2 interface extends the level 1 interface with the possibility of adding event handlers, which refer to level 1 programs. We call them "level 1" and "level 2," because level 2 programs can refer to the collection of all level 1 programs.

Event handlers are expected to be executed as independent *threads*, possibly in parallel. In order to communicate between them, we add to the level 2 interface the ability to create and use variables that represent the shared state between the event handlers. Event handlers access the shared variables, modify them and update the shared variables.

A first approximation for the type of an event handler referring to variable list l is

```
eventHandler : prod l \rightarrow IO GuiLev1Interface (prod l)
```

When translated into a native IO program, the event handler will read the state of all variables, obtaining value a : prod l. Then, it will execute program (eventHandler a) which, when terminating, returns an element a' : prod l which will then be written back to the variables.

Some modifications are needed: One is that eventHandler has two kinds of additional parameters: (1) some are to be executed when it is first created. Let the types of those parameters be B_1, \ldots, B_n . (2) Furthermore, we have some parameters which are used each time eventHandler is activated. Let their types be C_1, \ldots, C_n . The reason for the other modification is that one event handler might trigger events which other event handlers then handle. For this to work, one might need to update the variables before this trigger event is activated, so that the other handlers triggered make use of the updated state. The solution is to have a list of event handlers instead of having just one event handler. The event handlers in such a list will be executed in sequence. After each event handler in this list has been executed, the variables are updated. As a consequence, event handlers from other threads from now on will make use of the updated state. Therefore, we can update the state in one event handler of the list, and trigger an event in a later event handler of the list. A handler that refers to the revised state will handle the triggered event. Using these considerations, we obtain that the type of an event handler is as follows:

```
eventHandler : B_1 \to \cdots \ B_n \to List \ (prod \ l \to C_1 \to \cdots \ C_n \to lO \ GuiLev1Interface \ (prod \ l))
```

The level 2 interface GuiLev2Interface will be a state-dependent IO interface. The state of GuiLev2Interface is the list of variables obtained up to now, i.e., VarList: Set₁:

```
GuiLev2State : Set<sub>1</sub>
GuiLev2State = VarList
```

The level 2 interface has as commands level 1 commands, a command for creating a variable, and commands for adding a button handler, and an onPaint handler. The type of event handlers is as discussed before. The type of event handlers will refer to the variables created up to now; therefore, the commands for setting an event handler will depend on this state. Since the type of variables is an element of Set, the type of commands will be an element of Set₁:

```
\begin{array}{lll} \operatorname{data} \ \operatorname{GuiLev2Command} \ (s: \ \operatorname{GuiLev2State}) : \operatorname{Set}_1 \ \text{ where} \\ \operatorname{level1C} & : \ \operatorname{GuiLev1Command} \to \operatorname{GuiLev2Command} \ s \\ \operatorname{createVar} & : \ \{A: \operatorname{Set}\} \to A \to \operatorname{GuiLev2Command} \ s \\ \operatorname{setButtonHandler} : \ \operatorname{Button} \\ & \to \operatorname{List} \ (\operatorname{prod} \ s \to \operatorname{IO} \ \operatorname{GuiLev1Interface} \ \infty \ (\operatorname{prod} \ s)) \\ & \to \operatorname{GuiLev2Command} \ s \\ \operatorname{setOnPaint} & : \ \operatorname{Frame} \\ & \to \operatorname{List} \ (\operatorname{prod} \ s \to \operatorname{DC} \to \operatorname{Rect} \to \operatorname{IO} \ \operatorname{GuiLev1Interface} \ \infty \ (\operatorname{prod} \ s)) \\ & \to \operatorname{GuiLev2Command} \ s \\ \end{array}
```

Responses for level 1 commands are the corresponding level 1 responses. The response for the create variable command is the variable which was created. For all other commands the response is empty (an element of Unit). The type of responses is an element of Set:

```
\begin{array}{lll} \text{GuiLev2Response} : (s: \text{GuiLev2State}) \rightarrow \text{GuiLev2Command } s \rightarrow \text{Set} \\ \text{GuiLev2Response} &\_ (\text{level1C } c) &=& \text{GuiLev1Response } c \\ \text{GuiLev2Response} &\_ (\text{createVar } \{A\} \ a) &=& \text{Var } A \\ \text{GuiLev2Response} &\_ &=& &=& \text{Unit} \\ \end{array}
```

When creating a new variable, the return type will be a new variable; adding the new variable to the list of variables then updates this state. Otherwise the state will remain unchanged. Here, we have an example of a state-dependent interface where the next state not only depends on the command executed, but also on the response returned:

```
\begin{array}{lll} \text{GuiLev2Next}: (s: \text{GuiLev2State}) \rightarrow (c: \text{GuiLev2Command } s) \\ \rightarrow & \text{GuiLev2Response } s \ c \\ \rightarrow & \text{GuiLev2State} \\ \text{GuiLev2Next } s \ (\text{createVar } \{A\} \ a) \ \ var \ = \ \text{addVar } A \ var \ s \\ \text{GuiLev2Next } s \ \_ \ \_ \ = \ s \end{array}
```

Combining the above we obtain the resulting interface, which is an element of the second type level Set₂:

```
GuiLev2Interface : IOInterfaces

States GuiLev2Interface = GuiLev2State

Commands GuiLev2Interface = GuiLev2Command

Responses GuiLev2Interface = GuiLev2Response

nexts GuiLev2Interface = GuiLev2Next
```

When translating an event handler, which refers to variables l, into NativelO, we obtain a list of functions of type

```
f: prod l \rightarrow NativelO (prod l)
```

The function dispatch will translate each of these functions into an element of NativelO, which takes the variables, obtains a value *a*, executes *f*, and then writes back the variable:

```
dispatch : (l: \mathsf{VarList}) \to (\mathsf{prod}\ l \to \mathsf{NativeIO}\ (\mathsf{prod}\ l)) \to \mathsf{NativeIO}\ \mathsf{Unit} dispatch l\ f = \mathsf{takeVar}\ l\ \mathsf{native} \gg = \lambda\ a \to f\ a native \gg = \lambda\ a_1 \to \mathsf{putVar}\ l\ a_1
```

Dispatch will be used for writing event handlers which are possibly executed in parallel. Any dispatched handler of the form (dispatch $l\,f$) will empty the variables initially. No other dispatched handler then starts, because it waits until the variables are non-empty. When the first dispatched handler has finished, it writes the variables, allowing other dispatched handlers (which run in parallel) to start. Therefore, the execution of dispatched handlers of different threads is mutually exclusive. This is necessary since any intermediate changes of the state are not shared between threads.

The dispatching of a list of such functions is obtained by dispatching each individual function in sequence. Therefore, updates to the variables in one element of the list are shared to all other event handlers before executing the next element of the list. Since the variables are then non-empty, other threads accessing the variables at this point might interrupt execution and change the variables. Therefore, reading the variables again after having written them is necessary since they may have changed.

In the example given below in Section 10.4, we will make use of having a list of event handlers. When moving the spaceship, we will first update the coordinate of the spaceship, which changes the variable containing the coordinate. Then, we will call the repaint function, which needs to make use of the updated coordinates:

```
\begin{array}{ll} \operatorname{dispatchList}: (l:\operatorname{VarList}) \to \operatorname{List} \ (\operatorname{prod}\ l \to \operatorname{NativeIO} \ (\operatorname{prod}\ l)) \to \operatorname{NativeIO} \ \operatorname{Unit} \\ \operatorname{dispatchList}\ l \ [] &= \operatorname{nativeReturn}\ \operatorname{unit} \\ \operatorname{dispatchList}\ l \ (p::rest) &= \operatorname{dispatch}\ l \ p \ \operatorname{native} \gg = \lambda \ \_ \to \\ &= \operatorname{dispatchList}\ l \ rest \end{array}
```

We define translateLev1Local : $(c: GuiLev1Command) \rightarrow NativeIO$ (GuiLev1Response c) similarly to as we did in Section 9. The translation of level 2 commands makes use of the dispatch function. Since the event handlers are lists of functions, we need to apply the level 1 translation to each of the elements of this

list by using the operation map:

Note that the translation of (setButtonHandler *bt proglist*) uses nativeSetButtonHandler, which creates a new thread running a handler. The handler waits for a button event. If the button event happens the handler code is executed.

10.4 Example: A GUI controlling a space ship in Agda

We are going to introduce a program displaying a small spaceship controlled by buttons in Agda. This example is based on the Haskell program of the asteroids game (Leijen, 2004; Leijen, 2015). We will demonstrate only one button in this paper, which moves the spaceship to the right by a fixed amount. We will define three versions, which differ by the type of shared variables. These versions correspond to different methodologies of writing event handlers. The first one uses the data type of integers $\mathbb Z$ as its shared state. It represents the x-coordinate of the spaceship. The second one uses an object for storing the shared state. Here, we wrap $\mathbb Z$ into a cell object. More advanced examples would make use of more complex objects. Finally, the third one follows the common approach in object-oriented programming, namely to define the event handlers as methods of a common object.

All versions will define three event handling functions: onPaint, which handles the onpaint event for drawing the spaceship; moveSpaceShip, which is the first part of the button handler, which updates the state so that next time the spaceship is drawn its coordinates have changed; and callRepaint, which triggers a repaint event. The button will be handled by the two handlers moveSpaceShip and callRepaint in sequence. When the button event is triggered, first moveSpaceShip moves the spaceship by updating and sharing the state of the spaceship with new updated coordinates. Then, the callRepaint handler will trigger a repaint event that triggers the paint function to repaint the spaceship with the new coordinates.

It turns out that in all three versions the types of the event handling functions are—except for the type of the shared variable—the same. Furthermore, the definitions of the main program are identical. We will therefore define it at the end.

In the first version, the event handlers will read the x-coordinate, an element of \mathbb{Z} , and return the updated coordinate. Here, + is the constructor for \mathbb{Z} embedding \mathbb{N} into \mathbb{Z} . We define the type of the shared variable and its initial value:

```
VarType = \mathbb{Z}

VarInit : VarType

VarInit = (+ 150)
```

The event handling functions are as follows:

```
onPaint : \forall \{i\} \rightarrow \mathsf{VarType} \rightarrow \mathsf{DC} \rightarrow \mathsf{Rect} \rightarrow \mathsf{IO} \ \mathsf{GuiLev1Interface} \ i \ \mathsf{VarType} onPaint z \ dc \ rect = do (drawBitmap dc \ \mathsf{ship} \ (z \ , \ (+ \ 150)) \ \mathsf{true}) \ \lambda \ \_ \rightarrow \mathsf{return} \ z moveSpaceShip : \forall \{i\} \rightarrow \mathsf{Frame} \rightarrow \mathsf{VarType} \rightarrow \mathsf{IO} \ \mathsf{GuiLev1Interface} \ i \ \mathsf{VarType} moveSpaceShip fra \ z = \mathsf{return} \ (z + (+ \ 20)) callRepaint : \forall \{i\} \rightarrow \mathsf{Frame} \rightarrow \mathsf{VarType} \rightarrow \mathsf{IO} \ \mathsf{GuiLev1Interface} \ i \ \mathsf{VarType} callRepaint fra \ z = \mathsf{do} \ (\mathsf{repaint} \ fra) \ \lambda \ \_ \rightarrow \mathsf{return} \ z
```

In the second version, we define the variable via an object. Here, we will take the example of a simple cell, containing an integer with constructor cell **ZC**:

```
\label{eq:VarType} \begin{tabular}{ll} VarType & cell $\mathbb{Z}$C: $(z:\mathbb{Z})$ $\rightarrow$ VarType \\ objectMethod $(cell \mathbb{Z}$C $z$) get $=(z$, $cell $\mathbb{Z}$C $z$) \\ objectMethod $(cell \mathbb{Z}$C $z$) (put $z'$) $=(unit, $cell \mathbb{Z}$C $z'$) \\ varInit: $VarType \\ varInit = $cell \mathbb{Z}$C $(+ 150)$ \\ \end{tabular}
```

The event handlers are defined as before, but now they call methods of the simple cell object for getting and setting the coordinate. We omit their types since these are identical for all three versions of this program:

```
onPaint c dc rect = let (z, c_1) = objectMethod c get in do (drawBitmap dc ship (z, (+ 150)) true) \lambda \_ \to return c_1
```

```
moveSpaceShip fra\ c=
let (z\ ,\ c_1)= objectMethod c get (z\ ,\ c_2)= objectMethod c_1 (put (z+(+\ 20))) in return c_2
callRepaint fra\ c= do (repaint fra)\ \lambda\ _- 	o  return c
```

The third version makes use of an object, which has methods on PaintM, moveSpaceShipM, callRepaintM corresponding to the first three event handling functions:

```
data GraphicServerMethod: Set where
  onPaintM
                     : DC → Rect → GraphicServerMethod
  moveSpaceShipM : Frame → GraphicServerMethod
  callRepaintM : Frame → GraphicServerMethod
GraphicServerResult : GraphicServerMethod → Set
GraphicServerResult _ = Unit
GraphicServerInterface: Interface
Method GraphicServerInterface = GraphicServerMethod
Result GraphicServerInterface = GraphicServerResult
GraphicServerObject : \forall \{i\} \rightarrow Set
GraphicServerObject \{i\} = IOObject GuiLev1Interface GraphicServerInterface i
graphicServerObject : \forall \{i\} \rightarrow \mathbb{Z} \rightarrow GraphicServerObject \{i\}
method (graphicServerObject z) (onPaintM dc rect) =
     do (drawBitmap dc ship (z, (+150)) true) \lambda \rightarrow
     return (unit, graphicServerObject z)
method (graphicServerObject z) (moveSpaceShipM fra) =
     return (unit, graphicServerObject (z + (+20)))
method (graphicServerObject z) (callRepaintM fra) =
     do (repaint fra) \lambda \rightarrow
     return (unit, graphicServerObject z)
VarType = GraphicServerObject \{\infty\}
varInit: VarType
varInit = graphicServerObject (+ 150)
```

The event handlers will now simply call the methods of the shared object. The methods' result type is IO (Unit × GraphicServerObject), namely the product of the

response type Unit of the methods and of the type of the updated object, whereas the result of the event handlers needs to be IO GraphicServerObject. Therefore, we apply mapIO proj₂ to the results of those methods. Here, mapIO is a function which takes as arguments an $f:A\to B$ and an element of IO A and maps it to IO B by applying f to its return values:

```
onPaint obj\ dc\ rect = {\sf mapIO\ proj_2}\ ({\sf method\ }obj\ ({\sf onPaintM\ }dc\ rect))
{\sf moveSpaceShip\ } fra\ obj = {\sf mapIO\ proj_2}\ ({\sf method\ }obj\ ({\sf moveSpaceShipM\ } fra))
{\sf callRepaint\ } fra\ obj = {\sf mapIO\ proj_2}\ ({\sf method\ }obj\ ({\sf callRepaintM\ } fra))
```

The main program, which is identical for all three versions, does the following: It creates a frame and a button, adds the button to the frame, creates a variable of type VarType initialized by varInit, and sets the button handler and the onPaint handler to the event handlers defined. The program is then translated into a NativelO program:

11 Related work

Typestate-oriented programming (Garcia et al., 2014) is an extension of object-oriented programming (Strom & Yemini, 1986). It models state-dependent interfaces and object behaviour in imperative object-oriented programming. The states are given by a finite number of type states. Executing a method may change the state of an object. Although typestate-oriented programming can express the full range of object-oriented programming including aliases, it lacks a notion of dependent states that can be statically verified. Thus, the approach may catch only some errors statically, while still resorting to runtime checks or assertions (Garcia et al., 2014) to cover all errors. Furthermore, objects with an infinite number of states (such as our stack example with the state being the number of elements on the stack)

are out of the scope of typestate-oriented programming and other approaches to typestate.

Abadi & Cardelli (1996) introduce the ζ -calculus, which is similar to the λ -calculus, but for objects. There is a special second order quantifier called Self-quantifier $\zeta(X)\varphi(X):=\mu Y.\exists X<:Y.\varphi(X)$. This allows us to type objects and classes which make self-referential calls. Dependent types are not studied in their approach.

Coinduction in type theory: In the context of Nuprl's extensional type theory, simple coinductive types (Mendler et al., 1986) such as streams have been considered as greatest fixed-points of functors, using, in modern terminology, the following introduction rule:

$$\frac{\Gamma, n: \mathbb{N} \vdash e: F^n(\top)}{\Gamma \vdash e: \nu F}$$

In talking about the finite approximations $F^n(\top)$ of the coinductive type νF , it resembles sized types. However, in extensional type theory type checking is undecidable. Corecursive definitions have to be justified by proof, here by induction on the natural number n, whereas in Agda's sized types are built into the core language. One could, of course, say that Agda's sized types give the information needed to create such proofs.

Coquand (1994) introduces coinductive types via constructors as non-wellfounded trees—in contrast to the coalgebraic approach to define them via their destructors (Hagino, 1989; Setzer, 2012; Abel *et al.*, 2013). Coquand's work contains the definition of productivity of corecursive definitions and the guarded-by-constructors criterion to ensure productivity. This also extends to proofs as "guarded induction principle," but has limited expressivity, which is overcome by sized types as described in this article.

Coinductive types have been added to Coq's Calculus of Inductive Constructions following Coquand's proposal (Giménez, 1996). In Giménez' thesis, it was already noted that dependent pattern matching on coinductive data breaks subject reduction.

Giménez also suggested a type-based productivity check (Giménez, 1998) with similar proposals occurring at around the same time (Hughes *et al.*, 1996; Amadio & Coupet-Grimal, 1998). Since then, sized types have seen thorough theoretical exploration (Barthe *et al.*, 2004; Blanqui, 2004; Abel, 2007; Abel, 2008; Barthe *et al.*, 2008; Sacchini, 2013) and several prototypical implementations (Barthe *et al.*, 2005; Abel, 2010).

Component-based programming: Hancock & Hyvernat (2006)Granström (2012) (see also the component-based programming language IPL (Granström, 2016)) have suggested the use of interactive programs in component-based programming. A component is a combination of a server-side and a client-side program: It receives a request from the server and then interacts with the client-side until it has computed a response, which is then returned to the server-side. After the request ends, the component waits for the next server request. In this sense, an IOObject is a component having the object interface as a server-side interface and the IO-interface as a client-side interface. CounterCell (Section 7) can be considered as a component which communicates with a CellC object on its client-side.

Isabelle has many advantages since it integrates powerful automated theorem provers, especially Sledgehammer. Its built-in equality for coalgebras is already bisimilarity, making proofs much easier. However, it lacks dependent types. Strict positivity is more restrictive than in Agda which allows inductive–recursive (Dybjer & Setzer, 2003) and inductive–inductive definitions (Nordvall Forsberg & Setzer, 2010), which only make sense using dependent types. Lochbihler and Züst (2014) demonstrated how to use Isabelle as a functional programming language. Their type of interactive programs makes use of a type similar to our IO monad. Because of the lack of dependent types, this type has only one command with one type of arguments, and one result type. That could easily be generalised to finitely many methods, but not to the full generality in this paper. Blanchette et al. (2015) introduce friendly functions that are allowed on the right-hand side of corecursive definitions. They play a similar role to that of size preserving functions in our settings. However, size preserving functions seem to be more general.

Software Transactional Memory: The STM monad (Harris et al., 2008; Hackage, 2016) allows us to combine a series of actions such as writing and reading variables into one transaction. If such a transaction is interrupted, the transaction is rolled back to the state it was before it was executed. IO actions are not allowed inside such transactions. For this reason, the STM monad is not suitable for our approach, and we use manual locking via MVars instead.

Functional Reactive Programming (FRP) is another approach for writing interactive programs in functional programming languages. The idea is that input and output are given by input and output streams, and one has operations for creating new streams from existing ones. The elements of the input streams change as the input changes, which is then reflected in the elements of the streams defined from it, including the output streams. Therefore, the output reacts in response to the input. In connection with dependent types, FRP has been studied from the foundational perspective (Sculthorpe & Nilsson, 2009) and for verified programming (Jeffrey, 2013).

Phantom Types for Modeling Inheritance Relationships: wxHaskell offers bindings to the C++ GUI-library wxWidgets. The Haskell bindings model inheritance relationships (e.g., between widget classes in C++) as phantom types. However, wxHaskell cannot fully represent subtyping of object-oriented programming languages, as it relies on unsafe object casts. Phantom types are types with an additional type parameter which is not used by its constructors. For instance, we can state

data isPerson x data isStudent x data isPhDStudent x

If we had existential quantifiers over types, one could define

Person $= \exists x.$ isPerson x

Student = $\exists x. \text{isPerson (isStudent } x)$

PhDStudent = $\exists x.$ isPerson (isStudent (isPhDStudent x))

and then obtain: if a: Student then a: Person and if a: PhDStudent then a: Student and a: Person.

However, Haskell does not have existential quantifiers, so instead one defines

```
Person = isPerson ()
Student = isPerson (isStudent ())
PhDStudent = isPerson (isStudent (isPhDStudent ()))
```

Now, an element of Student is no longer an element of Person but we can define an upcasting function

```
upcast:Student \rightarrow Person
```

As we can equally define downcast: Person \rightarrow Student, the definition is unsafe. Furthermore, Student and Person are type synonyms, so they do not really have different constructors or (as objects) methods. One can distinguish them by having operations such as

```
studentNumber : Student \rightarrow \mathbb{N}
```

which is a postulated function and gets its implementation only from the corresponding C code. In this sense, this use of phantom types is unsafe, meaning we do not really have a type hierarchy but are using potentially unsafe casts which are not type-checked.

Algebraic effects and Idris: In the dependently typed programming language Idris, Brady has created an effects library based on algebraic effects (Brady, 2014). Algebraic effects were introduced in Bauer & Pretnar (2012, 2015). Effects can be considered as a version of state-dependent IO.

The type Effect of effects is a predicate on the sets *Result*, incoming *InResource*, and outcoming resources $OutResource : Result \rightarrow Set$. Written in Agda syntax, this reads as follows:

```
 \begin{array}{l} \mathsf{Effect} : \mathsf{Set}_1 \\ \mathsf{Effect} = (\mathit{Result} : \mathsf{Set}) \to (\mathit{InResource} : \mathsf{Set}) \to (\mathit{OutResource} : \mathit{Result} \to \mathsf{Set}) \to \mathsf{Set} \\ \end{array}
```

This can be considered as a state-dependent interface: The states are Set, the commands for a state s are the effects for which the result component is s, the responses are the *Result* component of the effect, and the next state is determined by the *OutResource* component:

```
effectTolOInterfaces: Effect \rightarrow IOInterfaces States (effectTolOInterfaces eff) = Set Commands (effectTolOInterfaces eff) s = \Sigma[ Result \in Set ] (\Sigma[ out R \in (Result \rightarrow Set)] (eff Result s out R)) Responses (effectTolOInterfaces eff) s (result, out R, op) = result nexts (effectTolOInterfaces eff) s (result, out R, op) = out R
```

In order to handle several effects in parallel, Brady introduces the type EFFECT, which consists of a state and a state-dependent interface, which can be simplified to

$EFFECT = Set \times Effect$

Then, he defines a second level of state-dependent interfaces Eff, which, as before, are state-dependent interfaces, but with (List EFFECT) as state. This type is not a closed data type but open for new commands to be registered, similar to IO in Haskell.

Furthermore, Brady introduces handlers, which are defined by referring to the predicate based data type Effect. If we replace this type by a set interface with the components $State^s$, C, R, and next, we obtain the following type of a handler, which depends on an operation $M: Set \rightarrow Set:$

```
(A: \mathbf{Set}) \rightarrow (s: State^{\mathbf{s}}) \rightarrow (c: C s) \rightarrow (f: (r: R s c) \rightarrow next s c r \rightarrow M A) \rightarrow M A
```

Using a handler, an IO program for the corresponding interface with return type A can be evaluated to an element of M A essentially by evaluating the handler for each effect. This allows, for instance, to write effectful programs having as effects an exception with return type A, and evaluate them to an element of Maybe A.

Brady introduces some very elegant syntax for defining and programming with effects. As in Bauer & Pretnar (2015), he allows expressions of normal data types to be formed from effectful programs (Brady uses a ! notation). This means that Idris code looks very similar to ML code where we have terms with side effects. However, this requires strict evaluation and that the order of evaluation is fixed.

12 Conclusion

We have seen how to introduce interactive programs and objects in Agda. We demonstrated how to program with them, including introducing GUIs with action listeners. We have seen the importance of state-dependent interactive programs and objects. One true example of a state-dependent interactive program was the creation of variables, where the new state depends not only on the issued command but also on the response given by the real world, namely the variable that was created. The example in Section 10 solved a problem in Agda: The original implementation in Haskell is rather low-level and requires the direct modification of variables. Our program solves this issue by using a shared object which can be accessed by the action listeners while they are executed. This is very close to the way this is actually implemented in standard object-oriented languages.

Our approach is a first step toward introducing object-orientation into dependent type theory. However, object-orientation consists of much more than simple objects. We have not shown how to define objects calling each other recursively; some work is already available in the third author's work (Setzer, 2006). The problem is to find a definition in such a way that it passes the termination checker – a method calling

itself immediately would result in black hole recursion. We have introduced a first step toward inheritance, namely to extend an object by additional methods reusing the original method implementations. However, future work is required to develop a methodology for overwriting existing methods. Proper inheritance would require a more expressive form of subtyping as it is currently implemented in Agda. The most challenging problem at this moment seems to be how to define objects dynamically on the heap. This would need some notion of pointers.

We hope that this article is a step toward having a programming language that has both dependent types and object-orientation. This would allow to combine both of these advanced programming paradigms, and to create a language in which programming is considerably easier and safer.
